3 ABSTRACT *Corynebacterium glutamicum* is widely used for the industrial production of  
4 amino acids, nucleotides, and vitamins. The shikimate pathway enzymes DAHP synthase  
5 (CgDS; Cg2391) and chorismate mutase (CgCM; Cg10853) play a key role for the  
6 biosynthesis of aromatic compounds. Here we show that CgCM requires the formation of  
7 a complex with CgDS to achieve full activity, and that both CgCM and CgDS are  
8 feedback regulated by aromatic amino acids binding to CgDS. Kinetic analysis showed  
9 that Phe and Tyr inhibit CgCM activity by inter-enzyme allostery, whereas Trp binding to  
10 CgDS strongly activates CgCM. Mechanistic insights were gained from crystal structures  
11 of the CgCM homodimer, tetrameric CgDS, and the heterooctameric CgCM-CgDS  
12 complex, refined to 1.1 Å, 2.5 Å, and 2.2 Å resolution, respectively. Structural details  
13 from the allosteric binding sites reveal that DAHP synthase is recruited as the dominant  
14 regulatory platform to control the shikimate pathway, similar to the corresponding  
15 enzyme complex from *Mycobacterium tuberculosis*.

## INTRODUCTION

The tight control and maintenance of appropriate intracellular concentrations of key metabolites is a general principle across all branches of life. Throughout evolution sophisticated regulatory mechanisms emerged both at the genetic level to vary gene expression (1) and at the protein level to control translation and protein turnover and to modulate the function of enzymes through allostery and post-translational modification (2-9). The result is a delicate balance ensuring that the organism is able to produce the essential nutrients and building blocks required for survival, without wasting precious resources once the metabolic needs have been met. One of nature's most powerful strategies for attaining this balance is through feedback inhibition, where a product of a biochemical pathway acts as an inhibitor for the enzymes that are required for its synthesis. This allows cells to dynamically and immediately adapt their metabolic activity to the environment in times of scarcity or abundance. A common mechanism of feedback control is allosteric regulation, whereby effectors bind to a region of an enzyme distant to the active site, resulting in a change in its activity (2, 6, 10-12).

A formidable example for this kind of feedback regulation is observed in the shikimate pathway (Fig. 1), a biosynthetic sequence for production of aromatic amino acids in bacteria, archaea, plants, fungi, and apicomplexan parasites (13), where the activity of several of the enzymes is regulated by allosteric feedback control (14, 15). DAHP synthase (DS) catalyzes the first step in the pathway, an aldol-like condensation of phosphoenolpyruvate (PEP) and D-erythrose-4-phosphate (E4P) to form 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP). As the first enzyme in the pathway, it

1  
2  
3 serves as a strategic point for feedback regulation (16). An example of this can be seen in  
4  
5 the extensively studied model organism *Escherichia coli*, which has three different DSs,  
6  
7 each subject to specific inhibition by one of the three aromatic amino acids (17-19).

31 **Figure 1. Shikimate pathway.** The first enzyme of the metabolic sequence towards  
32 aromatic compounds, DAHP synthase, catalyzes the condensation of D-erythrose-4-  
33 phosphate (E4P) and phosphoenolpyruvate (PEP) to 3-deoxy-D-arabino-heptulosonate-7-  
34 phosphate (DAHP). After another six enzymatic steps, the branch point compound  
35 chorismate (1) is either converted by anthranilate synthase to anthranilate and further to  
36 L-Trp, or by chorismate mutase to prephenate (2), an intermediate towards L-Tyr and L-  
37 Phe biosynthesis. Conversion of 1 to 2 is a pericyclic process with an endo-oxabicyclic  
38 transition state exhibiting charge separation at the ether bond to be cleaved. The chair-  
39 like transition state is well mimicked by Bartlett's transition state analog (TSA) 3 (20).

1  
2  
3 Another key enzyme of the shikimate pathway is the central branch point enzyme,  
4 chorismate mutase (CM). CM catalyzes the conversion of chorismate (**1**) to prephenate  
5 (**2**) *via* a Claisen rearrangement, a rare example of an enzyme catalyzing a pericyclic  
6 process (21, 22) (Fig. 1). This reaction commits chorismate to the synthesis of L-  
7 phenylalanine (Phe) and L-tyrosine (Tyr) as opposed to L-tryptophan (Trp). Due to the  
8 unique position at two diverging paths of the aromatic amino acid synthesis, CM is  
9 particularly important from a regulatory perspective, again exemplified by the two well-  
10 studied bifunctional CMs in *E. coli*, which are sensitive to feedback inhibition by either  
11 Tyr or Phe (23-26).

12  
13  
14 A different strategy for the sophisticated allosteric control of the shikimate pathway has  
15 recently been elucidated in *Mycobacterium tuberculosis*. Instead of bifunctional CMs, the  
16 open reading frame Rv0948 encodes a mono-functional CM (MtCM) that is utilized for  
17 the cytoplasmic synthesis of Tyr and Phe in *M. tuberculosis* H37Rv. Interestingly, MtCM  
18 shows only modest activity on its own compared to typical wild-type CMs (27-31).  
19 However, upon formation of a heterooctameric complex with DAHP synthase (MtDS,  
20 encoded by Rv2178c) (Fig. 2), crucial MtCM active site residues are repositioned, and  
21 the catalytic CM activity increases by more than a hundred-fold (32).

22  
23  
24 MtCM-MtDS complex formation plays a key role as a regulatory feature of the  
25 shikimate pathway in *M. tuberculosis*. The DS activity of MtDS is synergistically  
26 inhibited by the end products of the pathway (Phe, Tyr, and Trp), whereas the CM  
27 activity of the MtCM-MtDS complex, but not of MtCM alone, is synergistically inhibited  
28 by Phe and Tyr (32-36). In an evolutionary study on the MtCM-MtDS complex, we

could show that the activation factor by MtDS of MtCM variants is directly correlated with their response to the feedback inhibitors Tyr and Phe (37).

**Figure 2: Complex formation with MtDS preorganizes the MtCM active site for catalysis.** (a) Cartoon illustration of the active MtCM-MtDS heterooctameric complex (PDB: [1W1A](#) (32)). MtCM is colored in yellow and orange, the transition state analog (TSA) **3** in dark grey, and MtDS in shades of green to emphasize individual subunits.

22 All inhibitor binding sites are found in MtDS, distant from the MtCM-MtDS  
23 interface (36). Despite the distance, the presence of these inhibitors induces complex  
24 dissociation, as established by several biochemical and biophysical experiments (35, 36).  
25 This mode of indirectly regulating CM activity was only recently appreciated and  
26 characterized, and has been designated inter-enzyme allostery (36). Curiously, binding of  
27 the effectors to the complex only leads to negligible structural rearrangements of MtCM  
28 and MtDS, possibly causing tiny subunit misalignments that destabilize the  
29 heterooctameric assembly (36). It was also proposed that feedback inhibition may be the  
30 result of a change in dynamics of the enzymatic complex (33, 35, 36, 38). This is in  
31 keeping with a modern interpretation of allosteric regulation, suggesting that allosteric  
32 signaling can be driven by shifting populations of conformational ensembles, without  
33 necessitating clear structural rearrangements (6, 39-44).

49

50 Previous data and phylogenetic investigations indicate that the interaction between CM  
51 and DS could be a feature of shikimate pathway regulation unique to a few taxonomic  
52 orders within the bacterial class *Actinobacteria*, such as the *Corynebacteriales* (32, 36).  
53  
54  
55  
56  
57

1  
2  
3 *Corynebacterium glutamicum* is a non-pathogenic representative from the bacterial  
4 order *Corynebacteriales* and is used for the large-scale industrial production of  
5 amino acids, vitamins, and other food additives (45-48). Unlike *M. tuberculosis*, *C.*  
6 *glutamicum* ATCC 13032 has two genes coding for DS enzymes, a Type I DS (named  
7 NCgl0950 (45) or *cg1129* (49)) and a Type II DS (NCgl2098 (45) or *cg2391* (49)).  
8 Only the Type II DS is required for *C. glutamicum* growth in minimal media, indicating  
9 that only this enzyme is vital for amino acid production (50). The sequence identity  
10 between the CM of *C. glutamicum* (CgCM) and MtCM is 59%, and it is 65% between  
11 the Type II DS of *C. glutamicum* (CgDS) and MtDS. It has also been shown that MtDS  
12 can heterologously increase the activity of CgCM, which suggested that CM-DS complex  
13 formation plays a similar role in *C. glutamicum* as in *M. tuberculosis* (32). When the  
14 *C. glutamicum* enzymes were first studied (before *Brevibacterium flavum* was  
15 reclassified as *C. glutamicum* (51)), it was not possible to detect any CM activity in the  
16 absence of DS, pointing to a dramatic activating effect upon complex formation (52, 53).  
17 However, recent publications stated that CgDS did not enhance the catalytic activity of  
18 CgCM (54, 55). Thus, there is currently contradictory information in the literature  
19 regarding the regulation at one of the key branch points in the metabolism of this  
20 biotechnologically important bacterium.

43  
44  
45 Here, we use kinetic and structural approaches to elucidate similarities and differences  
46 between the CM-DS systems of *C. glutamicum* and *M. tuberculosis*. In particular, we  
47 were interested whether CgCM-CgDS is also subject to inter-enzyme allosteric  
48 regulation, and how its molecular mechanism compares to that previously established for  
49 MtCM-MtDS. Our findings established the crucial importance of CgCM-CgDS complex

## MATERIALS AND METHODS

### Assembly of gene expression plasmids

For the production of CgCM, we first used plasmid pKCGCM-HC (32), expressing the entire reading frame of the originally annotated *C. glutamicum* gene Cgl0853, provided with a 3' appended sequence encoding a C-terminal His<sub>6</sub>-tag. However, after gene expression and purification, this tagged CgCM variant showed two subpopulations of N-terminally degraded protein, shorter by 20 and 22 amino acids, as identified by LC-MS. Upon further scrutiny of the primary sequence (for a discussion about the most probable start codon, see (32)), the gene was recloned, this time using the third methionine (annotated as Met13 in gene Cgl0853) as the start codon, resulting in plasmid pKCGCM-H (4807 bp) (32). We regard this smaller 90 amino acid CgCM protein variant (shorter by 12 N-terminal residues relative to the annotated reading frame), which is devoid of any purification tag and which did not show any significant proteolytic degradation, as the native form of CgCM and we consequently used it throughout this work.

Plasmid pKCGDS-HN encodes an N-terminally His<sub>6</sub>-tagged version of the open reading frame of gene Cgl2178 (*i.e.*, with Met–His<sub>6</sub>–Ser–Ser–Gly fused to the start methionine). This CgDS gene construct was assembled after PCR amplification of chromosomal DNA of *C. glutamicum* ATCC 13032 (see (32) for DNA source and preparation). The PCR (94°C for 2 min; 25 cycles of 94°C for 30 s, 58.3°C for 30 s, 72°C for 90 s; followed by 72°C for 10 min) employed oligonucleotides 332-DSCG3N-S (TTGTGTCATATGCACCATCATCATCATCATTCTTCTGGTATGAGTGGACAGTTGATATCCCTAAA) and 333-DSCG4-N (TAGAACACTAGTTATTAGTTACGCAGCATTTCTGCAACG) resulting in a 1,442

1  
2  
3 bp PCR fragment. After digestion with *NdeI* and *SpeI*, the 1,424 bp PCR fragment was  
4  
5 ligated to the 4,529 bp *NdeI-SpeI* fragment of vector pMG211 (30) yielding CgDS  
6  
7 expression plasmid pKCGDS-HN (5953 bp).  
8  
9

10 The DNA sequences of the cloned genes were confirmed over their entire length by  
11  
12 DNA sequencing on an ABI Prism 3100 DNA Sequencer using two (for the CgCM gene)  
13  
14 and four (for the CgDS gene) custom made sequencing primers (Microsynth AG,  
15  
16 Balgach, Switzerland).  
17  
18  
19  
20

### 21 **Protein production and purification**

22  
23 Plasmids pKCGCM-H and pKCGDS-HN were used to overproduce the native  
24  
25 (untagged) CgCM and N-terminally His<sub>6</sub>-tagged CgDS, respectively, in *Escherichia coli*  
26  
27 KA13 (a strain deficient in CMs) (28, 56). A single colony of freshly transformed cells  
28  
29 was grown overnight in 5 mL LB medium containing 100 µg/mL sodium ampicillin (LB-  
30  
31 amp), and aliquoted for frozen stocks after adding glycerol to a concentration of 10%  
32  
33 (v/v).  
34  
35  
36  
37

38 A 50 mL LB-amp pre-culture was inoculated using scrapes of frozen stock, and grown  
39  
40 overnight at 37 °C. The LB-amp main culture (2x 1 L) was inoculated to an OD<sub>600nm</sub> of  
41  
42 0.05 and incubated at 110 rpm in a shaking incubator at 30 °C until an OD<sub>600nm</sub> of 0.5 was  
43  
44 reached. Then, gene expression was induced by adding IPTG to a final concentration of  
45  
46 0.5 mM. The production culture was incubated at 30 °C for approximately 18 h,  
47  
48 centrifuged at 6500 × *g* for 20 min (4 °C), and the cell pellet was frozen before  
49  
50 further processing.  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 For CgCM, the pellet was resuspended in 20 mM sodium phosphate buffer (pH  
4 8.0), containing 150  $\mu$ M PMSF and cOmplete protease inhibitor (Roche). Cells were  
5  
6 homogenized by two passes through a high-pressure homogenizer and  
7  
8 subsequently pelleted at 48000  $\times g$  for 30 min (4  $^{\circ}$ C). The lysate was loaded on a  
9  
10 5 mL HiTrap XL SP ion exchange column (GE Healthcare) and eluted with a gradient  
11  
12 from 0 – 500 mM NaCl. Homogeneous fractions were pooled, concentrated (Vivaspin  
13  
14 MWCO 3k), and further purified on a Superdex 75 300/10 column (GE Healthcare),  
15  
16 run with 20 mM Bis-Tris propane (1,3-  
17  
18 bis(tris(hydroxymethyl)methylamino)propane) (pH 7.5), 150 mM NaCl. Pure  
19  
20 fractions were concentrated after addition of 0.01% NaN<sub>3</sub> and stored at -20  $^{\circ}$ C.  
21  
22  
23  
24  
25

26 For CgDS, the pellet was resuspended in 50 mM Tris-HCl buffer (pH 8.2),  
27  
28 containing 300 mM NaCl, 5% glycerol, 2 mM  $\beta$ -mercaptoethanol, 20 mM imidazole,  
29  
30 150  $\mu$ M PMSF and cOmplete protease inhibitor (Roche). Cells were homogenized by  
31  
32 two passes through a high-pressure homogenizer and subsequently pelleted at  
33  
34 48000  $\times g$  for 30 min (4  $^{\circ}$ C). The lysate was loaded on a 5 mL Ni-NTA column (GE  
35  
36 Healthcare) and eluted with a gradient from 20 – 500 mM imidazole using a buffer  
37  
38 containing 50 mM Tris-HCl (pH 8.0), 300 mM NaCl, 150  $\mu$ M PMSF, 5% (v/v) glycerol,  
39  
40 100  $\mu$ M MnCl<sub>2</sub>, and 200  $\mu$ M PEP. Fractions containing CgDS were pooled and  
41  
42 dialyzed twice against 20 mM Tris-HCl (pH 7.0), 1 mM  $\beta$ -mercaptoethanol, 100  $\mu$ M  
43  
44 MnCl<sub>2</sub>, and subsequently loaded on a 5 ml HiTrap XL Q column (GE Healthcare) and  
45  
46 eluted with a gradient from 0 – 500 mM NaCl. Homogeneous fractions were pooled,  
47  
48 concentrated (Vivaspin MWCO 30k), and further purified on a Superdex 200 300/10  
49  
50 column (GE Healthcare), run with 20 mM Bis-Tris propane (pH 7.5), 150 mM NaCl,  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

0.5 mM TCEP (tris(2-carboxyethyl)phosphine), 100  $\mu$ M MnCl<sub>2</sub>, 200  $\mu$ M PEP. Pure fractions were concentrated after addition of 0.01% NaN<sub>3</sub> and stored at -20 °C.

### Enzyme activity assays

Chorismate was produced using a previously published protocol (57). *In vitro* CM activity assays were conducted at 30°C as previously described (32); briefly, the initial velocities ( $v_0$ ) needed for fitting to the Michaelis-Menten equation  $v_0 = k_{cat} \cdot [E] \cdot [S] / (K_m + [S])$  were obtained by continuously monitoring the consumption of chorismate at 274 nm ( $\epsilon_{274 \text{ nm}} = 2630 \text{ M}^{-1} \text{ cm}^{-1}$ ) or 310 nm ( $\epsilon_{310 \text{ nm}} = 370 \text{ M}^{-1} \text{ cm}^{-1}$ ) over a chorismate concentration range from 500  $\mu$ M to 3 mM. The  $k_{cat}/K_m$  of CgCM was determined at 310 nm in 50 mM Bis-Tris propane (pH 7.5), with a CgCM concentration of 950 nM. An apparent  $k_{cat}/K_m$  of CgCM-CgDS was determined at 310 nm in Bis-Tris propane (pH 7.5), 0.5 mM TCEP, 100  $\mu$ M MnCl<sub>2</sub>, 200  $\mu$ M PEP, with CgCM and CgDS concentrations held at 50 and 1000 nM, respectively, while the chorismate concentration was varied between 100  $\mu$ M and 2.6 mM.

For the assays measuring the effect of aromatic amino acids, effector concentrations were standardized to 25  $\mu$ M in all cases, CgCM concentration was 100 nM and CgDS concentration was 1000 nM, and chorismate (at 100  $\mu$ M) consumption was followed at 274 nm.

### Crystallization

Crystallization was generally performed and optimized in hanging-drop setups, except for the CgCM-CgDS complex, where sitting-drop setups were used following robotic

1  
2  
3 screening. CgCM was crystallized by adding 1  $\mu\text{L}$  protein solution (7.5 mg/mL) to 1  $\mu\text{L}$   
4 well-solution (100 mM  $\text{NH}_4$  formate (pH 6.6), 100 mM KSCN, 30% PEG 2000 MME),  
5  
6 at 20  $^\circ\text{C}$ . CgDS was crystallized by adding 1  $\mu\text{L}$  protein solution (10.0 mg/mL) to 1  $\mu\text{L}$   
7  
8 well-solution (100 mM Tris-Bicine buffer (pH 8.7), 13% MPD, 13% PEG 1000, 13%  
9  
10 PEG 3350, 2% tri-ethylene glycol, 200  $\mu\text{M}$  PEP, 100  $\mu\text{M}$   $\text{MnCl}_2$ ), at 4  $^\circ\text{C}$ . For the Trp  
11  
12 complex, the crystals were soaked by adding 1  $\mu\text{L}$  2 mM Trp to the drop at 25  $^\circ\text{C}$  and  
13  
14 incubating for 30 min before freezing the crystals.  
15  
16  
17  
18

19 Crystallization of the CgCM-CgDS-TSA complex was facilitated by microseeding.  
20  
21 Seeds were prepared by crushing poorly diffracting crystals in the drop with a glass rod,  
22  
23 and transferred to 50  $\mu\text{L}$  of the reservoir solution (100 mM Na-HEPES (pH 7.5), 200 mM  
24  
25  $\text{LiSO}_4$ , 25% PEG 3350). A glass bead was added and the suspension was mixed by  
26  
27 vortexing for 2 min. The resulting seed stock was diluted up to 1:1000. For  
28  
29 crystallization, 0.13 mM CgCM and 0.12 mM CgDS were mixed and incubated at 25  $^\circ\text{C}$   
30  
31 for 30 min with a few flakes of solid transition state analog (TSA) **3** (8-hydroxy-2-oxa-  
32  
33 bicyclo[3.3.1]non-6-ene-3,5-dicarboxylic acid) (20). After incubation, crystallization  
34  
35 experiments were set up with an Oryx 4 robot (Douglas Instruments, UK), mixing  
36  
37 0.15  $\mu\text{L}$  protein solution, 0.15  $\mu\text{L}$  1:10 seed stock, and 0.3  $\mu\text{L}$  well solution into a Swissci  
38  
39 2 sitting drop 96-well plate (and 50  $\mu\text{L}$  reservoir solution). Well-diffracting crystals were  
40  
41 obtained in 100 mM imidazole/MES buffer (pH 6.5), 30 mM each of ethylene glycol mix  
42  
43 (equal amounts of di-ethylene glycol, tri-ethylene glycol, tetra-ethylene glycol, penta-  
44  
45 ethylene glycol), 15% glycerol, and 15% PEG 4000. TSA was produced by Dr. Rosalino  
46  
47 Pulido according to a previously published procedure (58).

### Data collection, structure determination, and refinement

All data were collected at the ESRF, at beam line ID-29. The diffraction images were processed with *XDS* (59), and the resulting data merged with *AIMLESS* (60). 5HUC and 5HUE data sets were processed without averaging Friedel pairs to include anomalous information in the refinement. The resolution cut-off for the crystallographic data was chosen in accordance with the significance test employed by *XDS* (59). Instead of  $R_{\text{merge}}$ , we used the new gold standard for data quality control,  $CC_{1/2}$  (60-63). The structure was determined by molecular replacement (MR) with the program *Phaser* (64). For CgCM, terminally truncated MtCM (PDB-ID: 2VKL (32)) was used as MR model. For CgDS, a suitable MR model was built from MtDS (PDB-ID: 2B7O (65)) using *CHAINSAW* (66). For the CgCM-CgDS complex, the tetrameric MtDS as derived from the MtCM-MtDS complex (PDB-ID: 2W1A (32)) was used as a model for MR, and CgCM was subsequently built into the density manually. The structures were refined by alternating manual model building and automatic refinement using *Coot* (67) and *REFMAC5* (68), respectively. All programs from data merging to final structure polishing were part of the *CCP4* 6.5.019 package (69). A summary of the data collection and refinement statistics is given in Table 1. The atomic coordinates and structure factors have been deposited at the Protein Data Bank (70, 71) with accession codes 5HUB, 5HUC, 5HUD, and 5HUE. Buried surface areas were calculated with the PDBe PISA webserver (72). Structure images, superimpositions, and angle measurements were prepared using different versions of Pymol (Schrödinger, LLC), and reaction schemes were created with ChemDraw Professional 15.0 (PerkinElmer Informatics, Inc.).

## RESULTS

### Enzymatic activation of CgCM by CgDS

To address the contradictions within the literature about whether or not CgCM is activated by CgDS, we produced CgCM in its native (untagged) form and CgDS with an N-terminal His<sub>6</sub>-tag (see *Materials and Methods* for details). These protein formats are identical to the ones investigated previously for the *M. tuberculosis* system, where it was shown that the tag does not interfere with DS activity or CM activation (36). Enzymatic activity was determined by following the conversion of chorismate by CgCM alone and in the presence of CgDS.

The  $K_m$  of CgCM is too high ( $>3000 \mu\text{M}$ ) to obtain a meaningful fit of the experimentally attainable data for deriving  $k_{\text{cat}}$  and  $K_m$  from the Michaelis-Menten equation. However, it was still possible to accurately determine the ratio  $k_{\text{cat}}/K_m$  for isolated native CgCM as  $110 \text{ M}^{-1} \text{ s}^{-1}$  (Table 2). This value is within the same order of magnitude as the  $k_{\text{cat}}/K_m$  previously measured for N-terminal His-tagged variants of CgCM ( $370 \text{ M}^{-1} \text{ s}^{-1}$  and  $390 \pm 60 \text{ M}^{-1} \text{ s}^{-1}$ ) (32, 54), and 3-4 orders of magnitude below that of typical DS-independent CMs (27-31). Upon addition of CgDS, CgCM catalysis can be boosted 180-fold, proving a dramatic activation effect similar to that observed for the *M. tuberculosis* system (Table 2). This is in stark contrast to the data of the CgCM-CgDS study published recently, where no stimulation of CM activity was observed (54).

**Table 2:** Apparent catalytic parameters for the conversion of chorismate to prephenate

	$k_{\text{cat}}/K_m$ ( $\text{M}^{-1} \text{s}^{-1}$ )	Fold activation by DS
CgCM <sup>a</sup>	$111 \pm 7$	
CgCM-CgDS <sup>a</sup>	$(2.01 \pm 0.01) \times 10^4$	$182 \pm 12$

MtCM-MtDS <sup>b</sup>	$(2.4 \pm 0.6) \times 10^5$	$140 \pm 35$

<sup>a</sup> Measured in 50 mM BTP+, pH 7.5, at 50 nM CgCM and 1000 nM CgDS. Standard deviations were calculated from two different measurement series using independently purified CgCM preparations with the same CgDS stock that was used for crystallization. We noted that the apparent activation factors were up to twofold lower with other CgDS batches, possibly depending on varying degrees of intrinsic Trp occupancy (see below).

<sup>b</sup> Data from Sasso et al. (32)

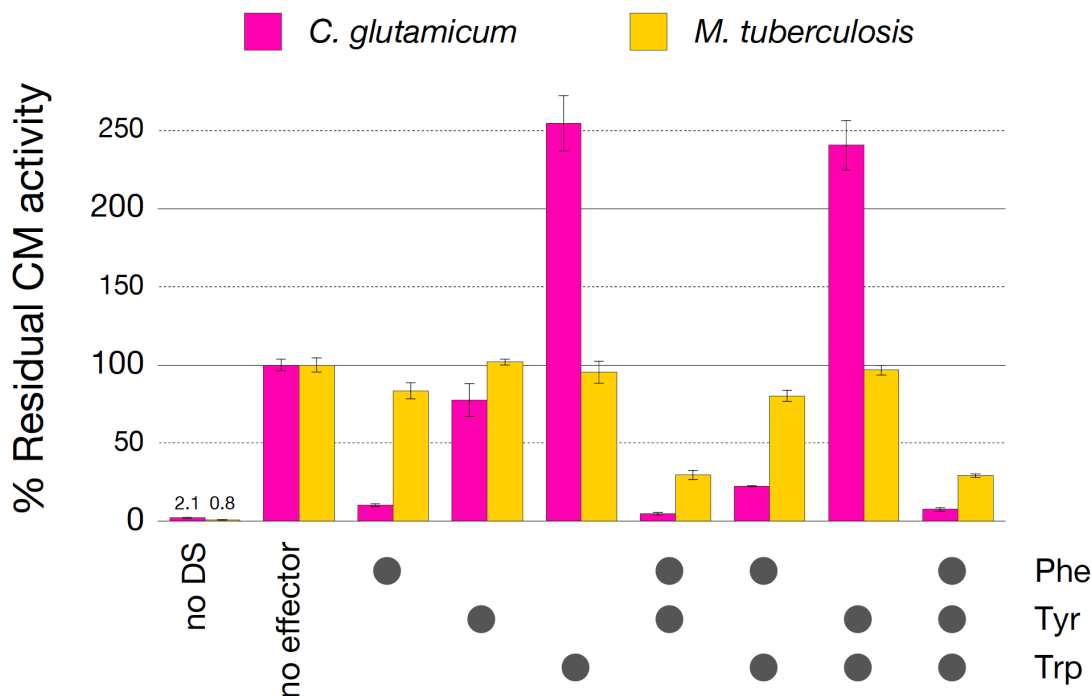

We noted that the CgCM activity of the CgCM-CgDS complex is very sensitive to a multitude of variables including the absolute concentrations of chorismate, CgCM, and CgDS. For instance, the specific activity of CM increases with higher protein concentration, even when preserving the ratio of CM:DS. We have also observed that at 50 nM CgCM, the CM activity was linearly dependent on the concentration of its complex partner and could not be saturated in the experimentally accessible CgDS concentration range of 1-4  $\mu\text{M}$ . This suggests that the  $K_{\text{d,app}}$  for CgCM-CgDS complex dissociation exceeds 4  $\mu\text{M}$  under our assay conditions.

### Allosteric regulation of the CgCM-CgDS complex by Phe, Tyr, and Trp

To investigate feedback regulation at the central branch point in the shikimate pathway of *C. glutamicum*, the effect of aromatic amino acids on the catalytic efficiency of CM in the CgCM-CgDS complex was studied. Additions of single aromatic amino acids as well as combinations thereof were tested to elucidate potential synergistic effects. The kinetic assays were carried out with native CgCM and His<sub>6</sub>-tagged CgDS, as it was shown previously that the correspondingly tagged homologous MtDS essentially retained the regulatory feedback properties of native MtDS (36).

Given the experimental difficulties for reaching saturation, we aimed to derive physiologically meaningful information by contemplating concentrations of enzymes and effector molecules that approximate the conditions in the producer organism. From literature data, we estimated the concentrations of DS for the three organisms *M. tuberculosis* H37Rv, *Mycobacterium bovis* BCG, and *C. glutamicum* ATCC 13032, to be approximately 3  $\mu\text{M}$  (73, 74). For CM, the only reliably established concentration was 300 nM for *M. bovis* (73). The chorismate concentration was estimated to be in the 40-70  $\mu\text{M}$  range for *C. glutamicum* (74, 75). Aromatic amino acid concentrations *in vivo* have been reported for *E. coli* to be 18  $\mu\text{M}$  Phe, 29  $\mu\text{M}$  Tyr, and 12  $\mu\text{M}$  Trp (76). As a compromise between experimentally accessible and naturally occurring concentrations, we used 1  $\mu\text{M}$  CgDS, 100 nM CgCM, 100  $\mu\text{M}$  chorismate, and 25  $\mu\text{M}$  of each aromatic amino acid effector for the kinetic studies on the regulation of the CgCM-CgDS complex. Figure 3 illustrates the strong activation of CgCM activity through CgDS. Both Phe and Tyr reduce the activity of CgCM-CgDS (with Phe having a much stronger inhibitory effect). When combined, the inhibition of the CM activity by Phe and Tyr is

synergistically enhanced. In contrast, Trp has a pronounced activating effect on the CM activity of CgCM-CgDS.

**Figure 3. Allosteric regulation of CM-DS complexes from *C. glutamicum* and *M. tuberculosis*.** The modulation of CM activity by Phe, Tyr, or Trp addition to the CM-DS complex (at 25  $\mu\text{M}$  of each effector) is indicated relative to the activity in the absence of the effector (defined as 100%). Left columns (pink) represent CgCM-CgDS measurements, columns to the right (yellow) plot the data for the MtCM-MtDS system published previously (36). For comparison, CM activity in the absence of a DS (and effectors) is shown on the left. Initial velocities were monitored at 30°C using 100  $\mu\text{M}$  and 23  $\mu\text{M}$  chorismate for CgDS-CgCM and MtDS-MtCM, respectively. Specific initial velocities ( $v_0/[\text{CM}]$ ) of chorismate consumption without effectors were  $1.55 \pm 0.06 \text{ s}^{-1}$  (100 nM CgCM; 1000 nM CgDS) and  $4.0 \pm 0.2 \text{ s}^{-1}$  (30 nM MtCM; 300 nM MtDS). Error bars on the *C. glutamicum* data reflect standard deviations of at least four separate

1  
2  
3 measurements (using 2 independently purified batches of the CM). Whereas the absolute  
4 values in experiments with an independent, presumably compromised CgDS isolation  
5 differed by about twofold, the relative effects of Phe, Tyr, and Trp on CM activity of the

measurements (using 2 independently purified batches of the CM). Whereas the absolute values in experiments with an independent, presumably compromised CgDS isolation differed by about twofold, the relative effects of Phe, Tyr, and Trp on CM activity of the respective complexes were approximately the same. All values are corrected for the spontaneous background reaction.

The general pattern of CgCM feedback inhibition is qualitatively similar to the one observed for the MtCM-MtDS complex, with Phe being a stronger inhibitor than Tyr (35, 36). However, these inhibitory effects are consistently more pronounced for the enzymes from *C. glutamicum* at the applied near- physiological concentrations (Fig. 3). For instance, the residual CM activity of the CgCM-CgDS complex is reduced to a mere 10% by 25  $\mu$ M Phe compared to 83% remaining activity for MtCM-MtDS. Also, synergistic inhibition by 25  $\mu$ M each of Phe and Tyr reduces the CM activity to 5% for CgCM-CgDS, which is almost as low as the activity of CgCM on its own (2% of the value for CgCM-CgDS, under the experimental conditions given in Fig. 3). The corresponding values for the MtCM-MtDS system were 30% (36) and 0.8% (this work), respectively. The most prominent difference to the *M. tuberculosis* enzymes is that the addition of Trp increases the CM activity of the CgCM-CgDS complex by a factor of 2.5 (Fig. 3), whereas Trp had no effect on MtCM-MtDS at the same effector concentrations and enzyme ratios (Cg 100:1000 nM vs. Mt 30:300 nM, for CM:DS ratios, respectively). The activating effect by Trp is in accordance with observations from early investigations of CgCM (77). Trp activation can (partially) offset inhibitory effects by the other amino acids (Fig. 3). In combination with Tyr, the activation by Trp is so prominent that the

1  
2  
3 weak inhibition by Tyr alone is completely mitigated, resulting in net activation (to  
4  
5 240%) relative to the CM activity of the CgCM-CgDS complex.  
6  
7

### 10 **Crystallographic analysis**

11  
12 To elucidate the molecular details of CgCM activation, we determined the crystal  
13 structures of CgCM, CgDS, and the CgCM-CgDS complex. The apo structure of CgCM  
14 was solved to 1.1 Å and refined to final  $R/R_{free}$ -factors of 0.17/0.22. For CgDS, data were  
15 collected for crystals with and without Trp soaked in (to 2.6 Å and 2.5 Å resolution,  
16 respectively, with  $R/R_{free}$ -factors of 0.25/0.28 and 0.24/0.25). The structure of the CgCM-  
17 CgDS complex was solved to a resolution of 2.2 Å ( $R/R_{free}$ =0.25/0.30), with a transition  
18 state analog (TSA in Fig. 1) bound in the active site of CgCM. For details on data  
19 collection and refinement statistics, see Table 1.

### 33 ***Crystal structure of CgCM***

34  
35 CgCM exhibits the typical structure of AroQ<sub>8</sub> subclass CMs, consisting of a  
36 homodimer with three  $\alpha$ -helices making up each protomer (Fig. 4a). The crystal structure  
37 contains one protomer per asymmetric unit. There are two active sites per homodimer,  
38 positioned at the protomer interfaces. The N- and C-termini of CgCM are disordered, and  
39 part of the loop connecting helices H1 and H2 close to the active site (residues 43-45;  
40 Fig. 4a) is characterized by weaker electron density and somewhat increased  $B$ -factors,  
41 despite interactions with a symmetry-related molecule in the crystal (Fig. S1).

**Figure 4. Structure of apo CgCM and comparison with apo MtCM.** (a) CgCM (PDB ID: [5HUB](#), this work; pink) and MtCM (PDB ID: [2QBV](#); orange/yellow (78)) in their non-activated dimeric forms. The helices of the CgCM protomers are labeled as H1/H1' (residues 11-42), H2/H2' (residues 50-70) and H3/H3' (residues 74-85). The

boxed area shows a close-up view of the loop connecting H1 and H2, illustrating the electron density (blue mesh) of residues shown as sticks ( $2mF_o - DF_c$  map, contoured at  $1.5 \sigma$ ). (b) Superimposition of the CgCM and MtCM enzymes, highlighting the unwound and extended helical segments, and the resulting differences in location and conformation of Arg46 and Arg58. (c) Superimposition of CgCM and MtCM active sites in the 'standard orientation' of Fig. 2c (TSA is superimposed from PDB ID: [2W1A](#) (32) for comparison, drawn in thin lines; stereo image). Arg18' is labeled with a prime and colored in a darker shade to show that this residue originates from the other protomer of the dimeric CM.

### ***Structural comparison of CgCM with MtCM***

Whereas the overall structures of CgCM (PDB ID: [5HUB](#), 1.1 Å resolution; this work) and MtCM (PDB ID: [2QBV](#) (78), 2.0 Å resolution, and PDB ID: [2VKL](#) (32), 1.65 Å resolution) are similar, the structures show clear differences close to the active site (Fig. 4). Many of these differences are probably not biologically relevant, however, due to extensive crystal contacts, which are different for the two structures (Fig. S1) (whereas CgCM crystallized in space group  $C2$ , MtCM crystallized in space group  $P4_32_12$ ). In CgCM, helix H1 is shorter by two turns, whereas helix H2 is elongated by two turns. This has implications for the connecting loop, which has a different orientation in the two structures (Fig. 4a and b), and, consequently, for the positioning of catalytically important residues (Fig. 2b and Fig. 4b and c). In particular, the side chain of Arg46, the residue assumed to play the most crucial role in catalysis by stabilizing the developing partial negative charge in the transition state (Fig. 1 and Fig. 2b and c) (79-81), is positioned far

1  
2  
3 away from the active site in CgCM (Fig. 4b and c). In contrast, in MtCM, the  
4  
5 guanidinium group of the corresponding Arg46 is less displaced relative to the  
6  
7 catalytically productive conformation assumed in the activated enzyme.  
8  
9

10 The main conclusion from the comparison of the apo CM structures is that the H1-H2  
11  
12 loops and the adjacent active site region appears to be malleable and easily adapt to  
13  
14 interact with other protein surfaces. This flexible nature is also reflected by the increased  
15  
16 *B*-factors in this region, not only for CgCM, but also for both available free MtCM  
17  
18 structures (PDB ID: [2QBV](#) (78) and PDB ID: [2VKL](#) (32)).  
19  
20  
21  
22  
23

### 24 ***Crystal structure of CgDS***

25  
26 As observed for MtDS structures (32-34, 36, 65, 82, 83), CgDS forms a homotetramer  
27  
28 (Fig. 5). Each protomer consists of a central catalytic TIM barrel, which contains the DS  
29  
30 active site featuring a  $Mn^{2+}$  ion and a PEP substrate molecule. The TIM barrel is  
31  
32 decorated with small additional domains at the dimerization and tetramerization  
33  
34 interfaces, like in MtDS (32-34, 36, 65, 82, 83) (Fig. 5). The N-terminus is oriented  
35  
36 towards the dimerization interface, which is known to contain the Phe-binding site in  
37  
38 MtDS (33, 34, 36, 82). However, in CgDS the N-terminus is not well defined by electron  
39  
40 density until residue 25; therefore, a tight interaction, as seen between the N-terminal  $\beta$ -  
41  
42 strands of MtDS (36, 65), is not observable in CgDS. Close inspection of the  
43  
44 tetramerization interface revealed electron density that can be attributed to Trp (Fig. S2).  
45  
46 The density is observed in the same pocket where Trp is known to bind in the MtDS  
47  
48 structures (33, 34, 36, 82).

5  
6 ***Crystal structure of the non-covalent CgCM-CgDS complex***  
7

8 The overall structure of the CgCM-CgDS complex shows a tetrameric assembly of  
9 CgDS, decorated with two CgCM dimers at opposing sides at the periphery to form a  
10 heterooctamer, analogous to its *M. tuberculosis* counterpart (32) (Fig. 6a and b). In  
11 contrast to the uncomplexed CM apo structures, the conformations of the CgCM-CgDS  
12 and MtCM-MtDS complexes with TSA are very similar (Fig. 6b) [backbone r.m.s.d. =  
13 0.37±0.03 Å between CgCM-CgDS (PDB ID: 5HUD, this work) and MtCM-MtDS (PDB  
14 ID: 2W1A (32))]. The similarity extends to the individual subunits (r.m.s.d. =  
15 0.41±0.02 Å for DSs and 0.43±0.03 Å for CMs).

4  
5 MtCM-MtDS (PDB ID: [2W1A](#) (32); yellow/orange) superimposed. Arg18' is labeled  
6  
7 with a prime and colored in a darker shade to show that this residue originates from the  
8  
9 other protomer of the dimeric CM.  
10

11  
12  
13  
14  
15 Also the catalytically relevant residues (Arg35, Ser39, Arg46, Val55, Glu59, and  
16  
17 Arg18', where the prime refers to the other protomer in the CM homodimer) in the  
18  
19 respective DS complexes superimpose well between MtCM and CgCM (Fig. 6c). All of  
20  
21 these residues adopt their active conformations, providing a structural explanation for the  
22  
23 apparent 180-fold rate acceleration measured for CgCM (Table 2). The biggest  
24  
25 conformational change is observed for the catalytic residue Arg46 (a 13 Å relocation of  
26  
27 C $\zeta$ ), which flips into the active site to interact with TSA through its ether oxygen and one  
28  
29 of its two carboxylates. The changes within CgCM coincide with an observable extension  
30  
31 of helix H1 and a shortening of helix H2 upon interaction with CgDS.  
32  
33  
34  
35

36  
37 When comparing the CgDS-CgCM interface with the corresponding CgDS apo  
38  
39 structure, we observe three major structural adaptations of CgDS: (i) formation of a salt  
40  
41 bridge between Arg223 and Glu468, avoiding clashes with CM residues 59-60 and 63;  
42  
43 (ii) reorientation of Gln402 to H-bond with the backbone NH of Gly90 at the C-terminus  
44  
45 of CgCM; (iii) reorientation of Asn472 affecting Arg409, which adopts a dual  
46  
47 conformation, clutching the C-terminal carboxylate of CgCM from two sides. In addition,  
48  
49 Glu461 slightly alters its conformation to avoid interference with CgCM residue His56.  
50  
51 All of these conformational changes favor the interaction with CgCM, promoting its  
52  
53 catalytically competent conformation. In particular, the CM C-terminus is reshaped to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 constructively interact with residues close to the CM active site (*e.g.*, Leu89 interacts  
4 with Leu54, less than 4 Å apart). Of the three described adaptations (i-iii), the first two  
5 are similar to those observed for the *M. tuberculosis* enzymes (36). The structural  
6 adaptations (iii) are not directly comparable because the C-termini of the two  
7 uncomplexed apo CMs adopt widely different conformations that are also affected by  
8 crystal contacts.  
9

10 Somewhat unexpected was the observation of additional helical fragments at the N-  
11 termini of two CgDS molecules (despite the fact that the N-terminus of CgDS, which is  
12 fused to a His<sub>6</sub> purification tag, is predicted to be flexible). These fragments were  
13 modeled as residues 7-17 of CgDS. They are located in solvent channels of the crystal  
14 and unlikely to affect complex formation or CgCM activation. As for the CgDS structure,  
15 we observed the presence of Trp in the CgCM-CgDS complex (see below), even though  
16 no Trp was added at any time for those structural studies.

### 34 ***Possible origin of CgCM activation by Trp***

35 All CgDS crystal structures, including the CgCM-CgDS complex, were found to  
36 contain Trp to different extents. As this compound was not added at any time during  
37 purification and crystallization, its most likely origin is co-purification from the cell  
38 lysate. Visual inspection of the electron density revealed that both apo CgDS and the  
39 CgCM-CgDS complex show significant occupancy of Trp in its binding pocket that was  
40 clearly increased upon soaking of CgDS crystals with Trp (see Fig. S2). This is also  
41 reflected by the *B*-factors of the Trp-ligand compared to interacting protein residues,  
42 which are essentially identical for the structure of the CgDS/Trp soak, whereas they are

2  
3 approximately 20 Å<sup>2</sup> higher (Trp compared to protein) for the CgCM-CgDS and apo  
4 CgDS structures (note that the occupancy was modeled at 100% for all three structures).  
5  
6 The two CgDS structures (and the DS part of the heterooctameric enzyme complex; Fig.  
7 S3) show no significant structural differences in the Trp binding sites. A close  
8 examination of the previously published structures of MtDS without Trp (PDB ID:  
9 2W1A (32), 3NV8 (82), and 2B7O (65)) suggests that it is unlikely that there are any  
10 trace amounts of Trp present in those structures, as there is no positive difference electron  
11 density. In one of the protomers (PDB ID: 2B7O (65)), the Gln239 side chain even  
12 points directly into the empty Trp binding pocket, where it would clash with Trp if bound  
13 there.

18  
19  
20  
21  
22  
23  
24  
25

26 The Trp binding site is located at the center of the CgDS tetramer, close to both  
27 dimerization and tetramerization interfaces, and at the same position as in MtDS (Fig. 7).  
28 This effector buries 291 Å<sup>2</sup> and 58 Å<sup>2</sup> from the involved two subunits (for comparison,  
29 307 Å<sup>2</sup> and 60 Å<sup>2</sup> are buried in MtDS) (Table S1). The hydrogen bonding pattern between  
30 Trp and CgDS is also analogous to that observed in the MtDS–Trp structure (PDB ID:  
31 3NUE (82)) and in fully inhibited MtDS (PDB ID: 5CKV (36)) (compare Fig. 7a and c).  
32  
33 As shown in Figure 7a, the indole NH group of Trp forms a hydrogen bond to the  
34 backbone carbonyl group of Ala202 of CgDS, the Trp carboxylate to the side chain of  
35 Lys133, and the Trp amino group to the backbone carbonyl groups of Ala250 and  
36 Ser247. The hydroxyl group of Ser247, in turn, forms a hydrogen bond across the  
37 tetramer interface to the backbone carbonyl group of Cys241 (Fig. 7a and b). In MtDS,  
38 the analogous interaction across the tetramer interface is mediated through Asn237,  
39 which provides an H-bond to the carbonyl oxygen of the homologous Cys231 (in one of

3 the MtDS subunits, Asn237 adopts alternative conformations, one H-bonding to Cys231  
4 and the other to the adjacent Gly232 residue) (Fig. 7c and d). Another difference between  
5  
6 CgDS and MtDS is the involvement of Leu207 in a prominent van der Waals interaction  
7  
8 with Trp in CgDS, a role played by Val197 in MtDS.

16  
17  
18  
19

20 Additional unique features distinguishing CgDS from MtDS are observed at the  
21 dimerization interfaces (Fig. 7b and d). Whereas in CgDS, a number of acidic residues  
22 accumulate at the center of the homotetramer (four copies each of Glu246 and, at some  
23 distance, of Asp245), in MtDS the homolog of Glu246 is an arginine residue (Arg236).  
24  
25 This basic residue extends its alkyl guanidinium side chain across the dimerization  
26 interface and interacts with Asn237 from a different DS protomer, a residue that is in the  
27 direct interaction sphere of Trp (Fig. 7c and d). The MtDS homotetramer in complex with  
28  
29 Trp (PDB ID: [3NUE](#) (82)) is clearly more structured at its core compared to its CgDS  
30 equivalent (PDB ID: [5HUE](#), this work), which exhibits very poor electron density for the  
31 central Glu246 carboxylate groups. Nevertheless, the distances across the DS core are  
32 essentially identical between the two structures (compare Figs. 7b and d).

41  
42  
43  
44

45 Previously, we reported a slight shift in the relative alignment of MtDS subunits  
46 (rotation by 1-2°) in the MtCM-MtDS complex as a result of the binding of the feedback  
47 inhibitors Phe and Tyr (comparison of PDB ID: [2W1A](#) (32) with [5CKX](#) (36)) (36). This  
48 realignment is hardly visible at the interface with CM, but more pronounced towards the  
49 DS dimer interface. MtDS in complex with Trp exhibits a realignment of similar  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 magnitude, but in the opposite direction (comparison of PDB ID: 2W1A (32) with  
4  
5 3NUE (82)), which brings the DS subunits closer together at the tetramer interface (not  
6  
7 previously described). In this work, we calculated relative subunit realignments slightly  
8  
9 differently, comparing helix axes at the DS tetramer interface. The results show similar  
10  
11 trends for the comparisons above, but give slightly larger values (3-4°). CgDS in complex  
12  
13 with Trp (PDB ID: 5HUE; this work) adopts a similar conformation as the MtDS-Trp  
14  
15 complex (PDB ID: 3NUE (82)). In comparison, apo MtDS (from PDB ID: 3NV8 (82)  
16  
17 rather than PDB ID: 2B7O (65), which contains a PEG molecule in the Phe-binding site)  
18  
19 is more “closed” towards the periphery, where CM would dock (Fig. S4). The relative  
20  
21 alignment of CgDS subunits in the Trp complex hence lies between that of the DS apo  
22  
23 form (derived from comparisons with the available MtDS structure PDB ID: 3NV8 (82))  
24  
25 and the CgDS complex with CgCM (PDB ID: 5HUD; this work) (Fig. S4), which may  
26  
27 suggest that Trp binding can prime CgDS for productive complex formation with CgCM  
28  
29 and thus promote CgCM activation.

## DISCUSSION

### **CgCM is activated by CgDS**

The kinetic and structural data presented here show that CgCM activity can be boosted by CgDS in analogy to what has been observed for the corresponding enzymes from *M. tuberculosis*. Even though the apparent  $k_{\text{cat}}/K_m$  for CgCM and CgCM-CgDS under the assay conditions is lower by an order of magnitude compared to MtCM and the MtCM-MtDS complex, respectively, the factor of activation afforded by DS is in a similar range (180-fold for CgCM<sup>1</sup> compared to 140-fold for MtCM). Thus, our results directly contradict the findings by Li *et al.* (54), who did not observe activation of CgCM by CgDS. We suspect that the activating effect by CgDS could have been hard to detect because the CgCM activity enhancement is very sensitive to a multitude of factors in addition to the CM:DS ratio, such as the absolute substrate and enzyme concentrations or the formats of the enzymes used. In this context, it must be noted that the His-tagged CgCM format used in the study by Li *et al.* (54) includes up to 31 additional amino acids at the N-terminus with respect to our untagged, and —compared to the Cgl0853 annotation— shorter CgCM. Even though the N-terminus of CgCM does not seem to be in close proximity of the CgDS surface (36), a 30% elongated CM version might show altered interaction behavior.

Activation of CgCM by CgDS was already reported much earlier, however. At that time, it was still assumed that the CM was split into two parts, one of which would be found fused to DS, forming a *bona fide* bifunctional enzyme (52, 53) The studies by

---

<sup>1</sup>Since Trp was found to additionally increase CM activity in the CgCM-CgDS complex, the extent of CgCM activation by CgDS alone may be somewhat overestimated due to possibly stoichiometrically bound residual Trp in CgCM-CgDS preparations. Any resulting basal Trp level (at most 0.5-1  $\mu\text{M}$ ) in the assays, however, is still much lower than the 25  $\mu\text{M}$  effector used for the kinetic studies.

1  
2  
3 Shio and Sugimoto (52), and Sugimoto and Shio (53) were carried out with the  
4  
5 organism *Brevibacterium flavum*, which was only later reclassified as *C.*  
6  
7 *glutamicum* (51), thus suggesting that they were actually characterizing the CgCM-CgDS  
8  
9 protein complex. Furthermore, we have shown previously that CgCM can be  
10  
11 heterologously activated with MtDS by more than an order of magnitude (32).  
12  
13  
14  
15  
16

### 17 **Structural similarity to CM-DS complex in *M. tuberculosis***

18  
19 Overall, the crystal structures of CgCM, CgDS, and the CgCM-CgDS complex are very  
20  
21 similar to those of their *M. tuberculosis* homologs. The clear similarities between the  
22  
23 CgCM-CgDS and MtCM-MtDS complexes extend to the CM active site and imply that  
24  
25 the activation of CM occurs by the same mechanism through optimizing the positioning  
26  
27 of active site residues (*e.g.*, Arg18', Arg46, and Val55). The largest structural differences  
28  
29 are found when comparing free apo CgCM with the corresponding MtCM. As detailed in  
30  
31 the *Results* section, those dissimilarities are likely caused by crystal contacts, but reflect  
32  
33 the malleability of the H1-H2 linker region. This property may also allow the active  
34  
35 conformation to be adopted relatively easily upon binding to CgDS.  
36  
37  
38  
39  
40  
41

### 42 **Regulation by inter-enzyme allostery – Similarities and differences**

43  
44 As for the MtCM-MtDS complex, association of CgCM with its complex partner  
45  
46 enables allosteric regulation by inter-enzyme allostery (36). It was demonstrated for the  
47  
48 *M. tuberculosis* system that binding of the feedback inhibitors Phe and Tyr to their  
49  
50 allosteric sites on DS dissociates the complex with CM, essentially resulting in shutting  
51  
52 off CM activity. We now report that the regulatory effects of the aromatic acids are even  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 more pronounced in *C. glutamicum* than in *M. tuberculosis*. This may partly be connected  
4  
5 with the much higher  $K_{d,app}$  of CgCM-CgDS ( $> 4 \mu\text{M}$ ) compared to the MtCM-MtDS  
6  
7 complex ( $\approx 140 \text{ nM}$  (32)). At the enzyme concentrations below  $K_{d,app}$ , as employed in the  
8  
9 kinetic measurements with CgCM (100 nM) and CgDS (1000 nM), a greater magnitude  
10  
11 of CM activity modulation would thus have been apparent compared to the data collected  
12  
13 at the saturating enzyme concentrations (above the  $K_{d,app}$ ) for the MtCM-MtDS system.  
14  
15 The magnitude of the regulation is, depending on the system studied, also quite sensitive  
16  
17 to the effector concentrations used in the assay. In fact, previous investigations on CM-  
18  
19 DS complex inhibition at 100-200  $\mu\text{M}$  of each amino acid (32, 35, 53, 84) gave  
20  
21 significantly different results than the 25  $\mu\text{M}$  used in this work, a concentration we  
22  
23 estimate to better reflect conditions encountered inside a bacterial cell (36, 76).  
24  
25  
26  
27

28  
29 The structural and kinetic data presented here extend the recently discovered novel  
30  
31 paradigm for regulation of the shikimate pathway (35, 36) to another member of the class  
32  
33 of *Actinobacteria*. Activation of CM by DS, and inter-enzyme allosteric inhibition by Phe  
34  
35 and Tyr represent clear similarities between *C. glutamicum* and *M. tuberculosis*.  
36  
37 However, there are also differences, in particular the observed activating effect of Trp on  
38  
39 CM catalysis for the CgCM-CgDS complex. Whereas activation by Trp has also been  
40  
41 reported for a CM from *B. flavum* (52, 53, 74), enhanced CM activity by Trp has not  
42  
43 been described for the previously characterized MtCM-MtDS system.  
44  
45  
46  
47  
48

### 49 **Trp enhances CgCM activation by CgDS**

50  
51 An activating effect of Trp on chorismate mutases is known to operate in yeast  
52  
53 (*Saccharomyces cerevisiae*) (85, 86) and plants (87, 88), and this cross-pathway  
54  
55  
56  
57

1  
2  
3 activation appears to be a general mechanism nature has developed to fine-tune the flux  
4 through the shikimate pathway. – But how does Trp enable the substantial activation of  
5 CgCM? In analogy to the *M. tuberculosis* system (33, 35, 36, 38), inter-enzyme allosteric  
6 regulation of CgCM may result from small realignments of the CgDS subunits or  
7 alternatively from differences in dynamics, caused by the binding of allosteric effectors.  
8 These changes need to be transmitted approximately 30 Å from the allosteric binding  
9 sites at the oligomerization interfaces of CgDS to its interface with CgCM. Certainly,  
10 optimal geometric and electronic complementarity at this interface between the CgDS  
11 homotetramer and the CgCM dimer is crucial for productive interaction and hence CM  
12 activation, but also the stability of the entire complex is likely to play a role.

### 29 **Model of feedback regulation of the shikimate pathway in *C. glutamicum***

30  
31 Trp is positioned at four locations at the DS tetramerization interface, each linking two  
32 DS subunits of the homotetramer (Fig. 7b). Since the tetramerization interface is  
33 characterized by a smaller interaction surface compared to the dimerization interface (855  
34 versus 1069 Å<sup>2</sup> without Trp), Trp could provide an additional surface to hold the tetramer  
35 together, potentially aiding complex formation with CM. Optimal arrangement of DS  
36 subunits is expected to promote binding of the CM homodimers and hence boost their  
37 catalytic activity. The realignment of DS subunits upon Trp binding is likely to contribute  
38 positively in this respect, as it opens up the CM docking site at its periphery (Fig. S4). In  
39 contrast, the binding of the feedback inhibitor Phe, which induces a register shift at the  
40 N-termini of the DS and tightly clamps Trp3 from two sides, as discussed  
41 previously (36), may lock the DS in an unfavorable conformation with respect to CM  
42

60

binding and activation. This tight “inter-locking” interaction with DS by Phe may dwarf the activating effect of Trp (Fig. 3), essentially shutting down CM activity (Fig. 8).

**Figure 8. Proposed mechanism of CgCM regulation.** From left to right: The first enzyme of the shikimate pathway, DAHP synthase, catalyzes the conversion of D-erythrose-4-phosphate (E4P) and phosphoenolpyruvate (PEP) to 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP). CM is positioned at the branch point of the shikimate pathway, towards synthesis of L-Phe and L-Tyr (and away from L-Trp). Its naturally poor activity is boosted by complex formation with DAHP synthase by 180-fold. L-Trp serves as allosteric activator, by promoting complex formation of CgCM with CgDS. It does so by binding to CgDS at the center of the DS tetramer, approximately 30 Å from the CM-docking site, stabilizing the tetrameric DS at close-to-optimal geometry for binding of CM. When the feedback inhibitors L-Phe and L-Tyr (with or without L-Trp) bind to their allosteric sites within the DS, the DS N-termini are “clamped” together. This leads to a conformational change at the DS binding interface and dissociation of CgCM from the CM-DS complex, and ultimately to downregulation of CM catalysis to its stand-alone mediocre activity.

### Why is CgCM regulation different from MtCM?

Whereas the regulation of CgCM and MtCM activity is generally similar, a key difference is the activating effect of Trp on CM catalysis in the CgCM-CgDS complex, which has not been observed for MtCM. Possible causes of this difference could be a higher affinity of Trp to CgDS, a more optimal geometry or electronic complementarity of CgDS for CgCM compared to MtCM-MtDS, or differences in the dynamics of the two systems. The fact that traces of Trp are observed in all CgDS structures (but not in MtDS), despite its absence during purification and crystallization, suggests that Trp may indeed be retained more strongly by CgDS<sup>2</sup>. Still, the Trp binding sites of CgDS and MtDS are rather similar (Fig. 7a and c), and do not suggest significant differences in binding affinities. There are two amino acid differences in CgDS compared to MtDS that could affect Trp binding, namely Ser247 (MtDS: Asn237) and Leu207 (MtDS: Val197), but their interactions with the ligand and the buried surface areas are comparable (Table S1).

We do, however, observe significant differences between the two structures at the DS tetramer core, which could influence geometry and dynamics. In CgDS, a cluster of acidic residues (four copies each of Asp245 and Glu246) dominates the tetramer core, whereas MtDS exhibits a more balanced profile of acidic (Asp235) and basic (Arg236) residues, and its two DS halves are more tightly connected across the dimer interface by interactions between Arg236 and Asn237 from a neighboring protomer (compare Figs. 7b

---

<sup>2</sup>Note that we cannot exclude with certainty that the complex with Trp has been selected for due to preferential crystallization.

1  
2  
3 and d). The differential amino acid interactions in the interface region are likely to affect  
4  
5 local conformations (note for instance the additional helical turns at the MtDS tetramer  
6  
7 core; Fig. 7d) as well as the overall tetramer alignment and dynamics, with possible  
8  
9 consequences for DS's ability to bind and activate CM. Electrostatic repulsion across the  
10  
11 CgDS tetramer core (Fig. 7b) may facilitate opening of the DS tetramer at its periphery  
12  
13 towards CM, explaining the strong activating effect of Trp in the CgCM-CgDS system,  
14  
15 whereas in MtDS, the interactions between Arg236 and Asn237, and between the Arg236  
16  
17 side chains from different protomers (Fig. 7d) may limit the dynamics and hence the  
18  
19 activation potential of Trp. Possibly, these dissimilarities lie at the heart of the observed  
20  
21 differences in feedback activation. It cannot be ruled out, however, that the chosen  
22  
23 experimental conditions, despite our best efforts, insufficiently model the biological  
24  
25 environment, and that Trp has some potential to promote CM activity in the CM-DS  
26  
27 complex in both systems. Cross-pathway activation by Trp would certainly make sense  
28  
29 biologically, as it enables the bacteria to efficiently redirect the metabolic flow at the  
30  
31 crucial shikimate pathway intermediate chorismate into other branches, as soon as the  
32  
33 cellular needs for Trp are met.

## 42 PERSPECTIVES

43  
44  
45 The knowledge gained about the regulatory details of the shikimate pathway could be  
46  
47 very useful for several reasons. *C. glutamicum* is an important bacterium for the  
48  
49 biotechnological production of amino acids, nucleotides, and vitamins. In fact,  
50  
51 metabolically engineered strains have been developed for the fermentation of L-  
52  
53 glutamate, which has been utilized for more than 50 years as an industrial food  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 additive (89). Elucidation of the structure and function of key shikimate pathway  
4  
5 enzymes are highly relevant for industrial innovations, as understanding of the natural  
6  
7 feedback regulatory mechanisms can inform strategies to eliminate potential bottlenecks  
8  
9 in large-scale biotechnological production. For instance, abolishing the feedback  
10  
11 inhibition of DAHP synthase in *Saccharomyces cerevisiae* by mutagenesis resulted in a  
12  
13 200-fold increase in extracellular aromatic amino acid concentration (90), and  
14  
15 corresponding rationally designed enzyme variants immune to the natural feedback  
16  
17 regulation may prove beneficial for *C. glutamicum* production strains, too. Furthermore,  
18  
19 since the here described CM-DS regulation mechanism is confined to just some orders of  
20  
21 the phylum *Actinobacteria*, which also includes pathogens responsible for diseases like  
22  
23 tuberculosis and leprosy (36), our insights into the molecular details of the regulation of a  
24  
25 central biosynthetic pathway may facilitate the development of pathogen-specific drugs.

## SUPPLEMENTARY FIGURES

**Supplementary Figure S1. Crystal contacts in apo CgCM.** The two panels show interactions of the CgCM (PDB ID: 5HUB, this work) H2 helix (close to the H1-H2 loop) to the symmetry related molecules in the crystal. The reference CgCM homodimer is shown in shades of pink, and the symmetry related molecules in shades of grey.

**Supplementary Figure S2. Comparison of electron density in CgDS Trp binding pockets.**

Top: CgDS "apo" structure (PDB ID: 5HUC, this work, 2.5 Å resolution). Middle: CgCM-CgDS complex (chain A, PDB ID: 5HUD, this work, 2.2 Å resolution). Bottom: CgDS Trp soak (PDB ID: 5HUE, this work, 2.6 Å resolution). The  $\sigma_A$ -weighted  $2F_o - F_c$  maps are contoured at 0.1 e/Å<sup>3</sup> (blue), 0.2 e/Å<sup>3</sup> (purple) and 0.3 e/Å<sup>3</sup> (red) for each of the structures (we compared absolute values rather than relative sigma-cutoffs to avoid bias due to different solvent contents, which are 29% for the CgCM-CgDS complex and 47% for the two CgDS structures). Resolution and quality of the CgDS structures in top and bottom panels is comparable, and the Trp ligand is clearly present at higher occupancy in the Trp soak. The structure of the CgCM-CgDS complex (middle panel) is better defined, in line with its higher resolution, however, the electron density of Trp is incomplete and of lower quality than that of the interacting protein residues, suggesting lower occupancy of the binding site as in the Trp soak. We estimate that Trp occupancy in the non-soaked structures is approximately equal, which is supported by a *B*-factor analysis of interacting residues.

**Supplementary Figure S3. Comparison of CgDS structures.** (a) CgDS (light gray, PDB ID: 5HUC, this work) superimposed with the structure of the CgDS-Trp soak (dark blue, PDB ID: 5HUE, this work). The superimposition was performed over all backbone atoms of the CgDS tetramers. (b) CgCM-CgDS-complex (violet blue and pink, PDB ID: 5HUD, this work) superimposed with the CgDS-Trp soak shown in (a). Superimpositions were performed over all backbone atoms of the CgDS A chains (subunit in the upper right position). The boxed area shows a close-up view of the CgCM-CgDS interface. Upon complex formation with CgCM, CgDS subunits moved further apart (indicated by the double-headed arrow), showing a slightly different relative tetrameric alignment of CgDS subunits compared to CgDS alone (with or without additional Trp). The angles were measured between the helices formed by residues 225-239 (CgDS) of two adjacent subunits (*i.e.*, the angles between the helix axes, shown as sticks in the helix centers). Mn<sup>2+</sup> ions are shown as purple spheres, PEP and Trp are shown as sticks.

**Supplementary Figure S4. Structural comparison of CgDS with MtDS.** CgDS-Trp soak (dark blue, PDB ID: 5HUE, this work) superimposed with the MtDS apo structure (green, PDB-ID: 3NV8 (1)) and the CgDS-CgCM complex (violet blue and pink, PDB ID: 5HUD, this work). Superimpositions were performed over all backbone atoms of the CgDS A chain (subunit in the upper right position). The boxed area shows a close-up view of the binding interface for CM (double-headed arrow). The angles were measured between the helices formed by residues 215-229 (MtDS) or residues 225-239 (CgDS) of two adjacent subunits (*i.e.*, the angles between the helix axes, shown as sticks in the helix centers). The relative alignment of CgDS subunits in the Trp complex lies between that of the MtDS apo form and the CgDS complex with CgCM. Mn<sup>2+</sup> ions are shown as purple spheres, PEP and Trp are shown as sticks.

## SUPPLEMENTARY TABLE

### CgDS - PDB I D 5HUE

Tr p		ASA (Å <sup>2</sup> )	BSA (Å <sup>2</sup> )
TRP	1	355.3	290.5
TRP	1	355.3	57.6

CgDS		ASA (Å <sup>2</sup> )	BSA (Å <sup>2</sup> )
LEU	117	3.7	3.7
ALA	120	2.7	2.7
VAL	121	14.6	5.8
THR	124	54.0	14.6
PRO	130	86.6	4.4
VAL	131	9.9	4.7
LYS	133	33.4	28.6

ASN	237	129.8	27.8
LEU	238	29.2	9.1
THR	240	60.3	8.7
ALA	241	26.0	15.1
GLU	242	67.6	1.0
PHE	227	136.7	0.5
ALA	230	86.6	6.1
CYS	231	84.0	50.3

**Supplementary Table S1. Surface area of Trp interface in CgDS and MtDS.** Surface area of the Trp ligand bound to either CgDS (PDB ID: 5HUE, this work) or MtDS (PDB ID: 3NUE, (1)), calculated per interacting residue. ASA = accessible surface area; BSA = buried surface area; interactions in the main binding pocket are shaded in green, interactions with the second subunit are shaded in yellow. The surface areas were calculated using the PDBe PISA Server (2).
