Biographical sketches:

Willy Pedersen is professor of sociology at University of Oslo. His research interests include nicotine dependence, use of alcohol and illegal substances, crime, social marginalization and sexual behavior.

Eivind Grip Fjær is a doctoral student in sociology at the University of Oslo. His dissertation explores alcohol consumption, rituals and the moral regulations of youth parties.

Paul Gray is a Senior Lecturer in Criminology in the Department of Sociology at Manchester Metropolitan University, United Kingdom. His research interests include youth offending, resettlement and substance use.

Tilmann von Soest is professor at the Department of Psychology, University of Oslo. His research interests include mental health, health behavior, and self-worth among adolescents and young adults.

Abstract

Introduction: International drug policy has been based on the premise that illegal drugs are more harmful than legal substances. Here, we investigate how students in the UK and Norway perceive possible harms related to tobacco and alcohol - which are legal; and cannabis - which is illegal.

Methods: Social science undergraduates at a university in the UK (N = 473) and Norway (N = 472) completed an anonymous survey. They were asked to rate the harms of the three substances across five domains: (i) physical harms; (ii) mental health conditions; (iii) dependence; (iv)
injuries; and (v) social consequences. Bivariate and multivariate analyses were used to compare the relative harms of the three substances across all the domains, as well as possible differences between participants from the UK and Norway.

**Results:** Tobacco was rated as most harmful with regard to physical harm and dependence; alcohol as most harmful with regard to injuries and social consequences, while cannabis was rated as most harmful with regard to mental health. The total harms scores for alcohol were highest, slightly above those of cannabis. British students reported higher tobacco and alcohol harm scores than Norwegian students, while the opposite pattern was true for cannabis.

**Conclusions:** The students’ ratings did not appear to be much influenced by the legal status of the substance in question, with the legal substance alcohol rated as more harmful than the illegal substance cannabis. The findings may imply that young people in the years to come may be less supportive of a traditional drug policy based on criminalization, at least when it comes to cannabis. At the same time, one may hypothesize that neither a very liberal alcohol policy may receive much support, as they were well aware of the possible harms associated with alcohol.

Key words: Drug harms, harm scale, tobacco, alcohol, cannabis, alcohol policy, drug policy
Introduction

International drug control is, in principle, justified by the presumed harms of the use of psychoactive substances, as described in various UN conventions (Room, 2006). Based on these conventions, a wide variety of substances have been labelled as illegal and come under international control. As a result, they have also been treated and described through a different rhetoric than those surrounding legal substances such as tobacco and alcohol. However, in two recent articles David Nutt and co-workers developed so-called “rational drug harm scales”, where panels of experts rated substance harm using “multi criteria decision analyses” (Nutt, King, & Phillips, 2010; Nutt, King, Saulsbury, & Blakemore, 2007). The main finding from the studies was the poor correlation between the legal classification of drugs and experts’ harm scores. Alcohol was rated as the most harmful substance, well above the most prevalent illegal substance, cannabis. To a large degree, the high score of alcohol was related to harms experienced by others rather than the users themselves. The study was later replicated with drug experts from different countries throughout the EU with basically the same results (van Amsterdam, Nutt, Phillips, & van den Brink, 2015). Researchers from France (Bourgain et al., 2012) and the Netherlands (van Amsterdam, Opperhuizen, Koeter, & van den Brink, 2010) also reported similar results.

All these studies have been criticized on a number of grounds (see e.g.: Caulkins, Reuter, & Coulson, 2011; Fischer & Kendall, 2011). One type of criticism is related to the method’s vulnerability to experts’ subjective judgements, another to the failure of the ratings to disaggregate harms related to the drugs themselves from those resulting from the policy in question (e.g. the criminalization of use and possession of cannabis). Nonetheless, most scholars have welcomed this line of research as a fruitful corrective to typical perceptions of legal and illegal drugs and their associated harms.
Drug users’ own perceptions of harm have also been investigated. A web-based survey of a sample of active drug users from the UK (Morgan, Muetzelfeldt, Muetzelfeldt, Nutt, & Curran, 2010), found results similar to those of Nutt and co-workers (Nutt et al., 2010; Nutt et al., 2007), with alcohol ranked among the more dangerous substances while cannabis was ranked among the least dangerous. However, few studies have investigated drug harm perceptions outside expert groups and such highly selected samples. Norway is an exception; as such perceptions have been monitored in population-based studies from the mid-1960s (Brun-Gulbrandsen, 1970; Skretting, 1990; Skretting & Rise, 2011). Contrary to the reports by Nutt et al. and in line with the ideas behind the UN conventions, in these studies illegal substances have always been rated as much more harmful than legal substances. Indeed, the illegal substances which have been rated have changed over time, reflecting historically changing patterns of prevalence, with morphine and LSD being included in the 1960s, while heroin was first introduced in the 1980s. Cannabis has been rated throughout all the studies and has remained in the “dangerous” illegal substance group, well ahead of alcohol and tobacco. However, a recent study of a selected sample of Norwegian students indicates possible changes: In the urban Oslo area, students rated harms associated with cannabis as slightly lower than those related to the use of alcohol, even if this pattern was not as clear among students in a rural area of the country (author citation removed).

Several other research groups have also presented alternatives to the perspectives underling the UN conventions, even though these reports have got limited public attention. For example, in the late 1990s, a group of researchers compared the severity of health effects for “heavy users of different substances”. Alcohol ranked highest, with tobacco and heroin ranked in the middle and cannabis ranked at a clearly lower level (Hall, Room, & Bondy, 1999). At the same time, a French research committee ranked substances according to their “toxicity”. Alcohol, tobacco, cocaine and heroin were rated as “very strong”, while cannabis was rated as “very
weak”. However this report resulted in heated public debate, due to the sensitivity of the topic (Room, 2006). Another approach when comparing the risk of different substances is called the margin of exposure (MOE) approach. The MOE is defined as the ratio between the toxicological threshold or median lethal dose and estimated typical human intake. A recent study based on this approach identified alcohol as the only substance posing “high risk” at a population level, while cannabis was associated with “low risk” (Lachenmeier & Rehm, 2015).

Generally, there seems to be an increasing disjunction between what scientists are willing to agree with, and what the political process is willing to accept in the drug policy area. For example, a WHO committee twice suggested downgrading THC (an active ingredient in cannabis) as a medication under the 1971 convention, but both times the Commission on Narcotic Drugs rejected the recommendation (Room & Lubman, 2010). Nevertheless, during the last decade there has been mounting pressure against international drug policy. Drug policy reform is higher on the international policy agenda than ever before, and in 2016 the United Nations will have a special session on drug policy (UNGASS 2016). More than one in three U.S. states have now legalised cannabis in medical programmes, while four US states, as well as Uruguay, have also legalised cannabis “for pleasure” (Room, 2014). Justin Trudeau recently won the election in Canada, on a program to legalize cannabis (Guardian, 2015). Furthermore, an increasing proportion of opiate addicts are enlisted in opioid maintenance programmes, creating new concepts of “harm reduction” and “illness” to replace “crime”. Thus, there are signs of a deep paradigm shift in drug policy, as well as a shift in perceptions of the dangers associated with illegal drugs in general, and cannabis specifically.
The aim of this study is to investigate harm rankings of the three most prevalent psychoactive substances – tobacco, alcohol and cannabis – among university students from the UK and Norway. In both countries tobacco and alcohol are legal, whereas cannabis is illegal. Although the prevalence of smoking is considerably higher among adults (Ng et al., 2014) and adolescents (ESPAD, 2012) in the UK than in Norway, today both countries are among those with the most restrictive tobacco policies - even though Norway started out with an intense control policy earlier than the UK (Joossens & Raw, 2006). Also, smoking has become increasingly denormalised in both countries (Hammond, Fong, Zanna, Thrasher, & Borland, 2006; Sæbø, 2015). Indeed tobacco consumption in Norway is currently shifting to snus, a smokeless, low-nitrosamine product, regarded by experts as considerably less harmful than cigarettes (author citation removed). Snus is banned in all EU countries except Sweden.

The UK and Norway are both situated in the cultural North-West of Europe. Here, heavy drinking is more common than the typically frequent consumption of low quantities of alcohol found in the Mediterranean countries (Kuntsche, Rehm, & Gmel, 2004). In both countries, about a third of drinking occasions among adolescents lead to intoxication (Babor et al., 2010, p. 35). Still, per capita alcohol consumption in Norway is clearly lower than in the UK (WHO, 2014, pp. 228, 246). Even though it has gone in a more liberal direction in the last few years, alcohol policy in Norway is still rather strict (Karlsson & Österberg, 2007), compared to the UK (Nicholls & Greenaway, 2015). Still, the public concern regarding “binge drinking” that has pervaded the UK in the last decade or so is unmatched in Norway (Plant & Plant, 2006; Szmigin et al., 2008).

The prevalence of cannabis use has also traditionally been higher in the UK than in Norway; however over the last decade the gap between the two countries has decreased
somewhat (EMCDDA, 2015b). Cannabis policy in the UK was the subject of an attempt to reclassify the drug from a class B to a class C drug in 2004: this was reversed in 2009 (Monaghan, 2014). In contrast, Norway has had, and still has, a clearly stricter cannabis policy than the UK (Hauge, 2013).

Thus, generally there seems to be a somewhat higher level of the use of all three substances in the UK than in Norway, and the UK traditionally has had a somewhat more liberal policy in relation to all three substances even if these differences have diminished somewhat.

**Aim of the study**

In this study, we ask:

1. How do students from the UK and Norway rank the three most prevalent psychoactive substances - tobacco, alcohol and cannabis - on different dimensions of harm?
2. Are there significant differences in harm perceptions between students from the UK and Norway?
3. To what degree do harm ratings reflect students’ own substance use?

**Methods**

*Sample and procedure*

The sample consisted of social science undergraduates (studying sociology, psychology, and criminology) at two large universities in the UK and Norway. The universities are situated in cities of approximately the same size. Students were asked to complete a short questionnaire which was administered anonymously. The first page provided information about the study aims, the anonymous nature of the study, and that participation was voluntary. A total of 945 students participated, 473 from the UK, 472 from Norway. We did not register non-participants but
attrition was negligible based on our observations. The study was approved by the Internal Review Board for Research of the Department of Psychology at the Norwegian university.

Measures
Based on Nutt et al. (Nutt et al., 2010), we measured five domains of possible drug harms, with the following introduction: “We are interested in your opinion on how harmful tobacco, alcohol and cannabis can be in different areas of life. Answer on a scale from 1 to 6, from “Not harmful” to “Very harmful”.” We then listed the following areas: (i) physical harms (e.g. cancer, cardiovascular diseases, lung diseases, liver diseases); (ii) mental health conditions (e.g. learning disabilities, apathy, anxiety, depression, psychosis); (iii) dependence (e.g. problems with quitting use, despite serious consequences); (iv) injuries (e.g. drowning, falls or traffic accidents, quarrels, violence); and (v) social consequences (e.g. break-up of family relations, educational problems, problems with the police). One score was given for each substance on each domain. We also calculated a mean score for each substance. Internal consistency was 0.67, 0.75 and 0.82 for tobacco, alcohol and cannabis harm ratings, respectively.

We then asked: “Do you smoke?” Response options were on a 5-point scale: 1 – “No, never”; 2 – “Have never smoked regularly and do not smoke at all now”; 3 – “Have smoked regularly, but have quit altogether now”; 4 – “Smoke, but not daily”; and 5 – “Smoke daily”. Smoking was dummy-coded so that those who had never smoked, or only smoked irregularly previously, were contrasted with those who had smoked regularly in the past but not now, those who reported non-daily smoking, and those who reported daily smoking. We also asked: “How many times have you drunk alcohol in the course of the previous 12 months?” Response options were on a 5-point scale from “Never” to “More than three times a week”. For some analyses, we dummy-coded alcohol use by contrasting respondents who had not drunk any alcohol in the
previous 12 months with those who had drunk alcohol a few times a month or less, approximately once a week, and more than once a week, respectively. Finally, we asked two questions about cannabis: “Have you ever used cannabis?”, with response options from “No” to “More than 50 times”, and “How many times have you used cannabis in the course of the past 12 months?”, with response options from “None” to “More than 50 times”. Again, dummy coding was used to contrast respondents with no prior experience with cannabis use and those who had used cannabis previously but not during the last 12 months, with those who had used it once during the last 12 months, 2–10 times, 11–50 times, or more frequently during the last 12 months. We also asked to what religion or denomination the respondent belonged, with response options: “No religion”; “Christianity”; “Islam”; or “Other religion”. In all analyses, we dummy-coded religious affiliation as three variables on which we contrasted no religion with the other three response options.

Statistics

T-tests were conducted to examine differences in harm ratings according to gender and country. Analyses of variance (ANOVA) and analyses of covariance (ANCOVA) were utilised to examine whether harm ratings differed for different drugs and between genders and countries. Moreover, we investigated whether drug type, gender and country interacted in predicting harm ratings. Finally, multiple linear regression analyses were conducted to investigate the combined effects of gender, country, participants’ own substance use and religion on harm ratings.

Results

In Table 1, descriptive statistics of use of drugs are presented. Note that more participants from the UK were regular smokers compared to Norway, and that they also had a considerably higher
level of cannabis use. Participants from Norway had a slightly higher prevalence of regular alcohol use. However, the dispersion of alcohol use differed between the two countries: In the UK, more persons had abstained completely from alcohol in the last 12 months compared to Norway (21.1 % compared to 8.1% of the Norwegian sample), while at the same time a larger percentage had used alcohol 2-3 times a week or more (28.0 % versus 13.2 % in the Norwegian sample).

In Figure 1, mean harm ratings for all three substances across all five domains are shown for participants in both countries. We note that tobacco was rated as most dangerous when it comes to physical harm and dependence. Alcohol had the highest score with regard to injuries and violence and cannabis was ranked as more dangerous than alcohol when it comes to mental health consequences. On the total harm score, alcohol was rated slightly higher than cannabis. When comparing total harm scores between the two countries (using t-tests), we found that participants from the UK rated tobacco and alcohol as more harmful than participants from Norway (p < 0.01), while the opposite pattern was true for cannabis (p < 0.001).

As a next step, analyses of variance and covariance were conducted to examine differences in harm ratings according to drug type, country and gender in greater detail. By including drug type, country and gender as factors, main effects of these three variables on harm ratings and mean scores across all five domains were able to be investigated. Thus providing information about differences in the level of harm ratings between drug types, country and gender. As shown in Table 2, for all six measures, ratings of harm differed significantly according to drug (i.e. the main effects of drug type were significant). Additional Bonferroni post-hoc tests showed that ratings of harm differed significantly between all three drug types for all six measures (p < .001). We note that physical harm and dependence scores were highest for tobacco. Mental health consequences were regarded as most severe for cannabis use, while injuries and damages
as well as social consequences were regarded as most serious in relation to alcohol use. Overall, alcohol was regarded as most harmful.

All main effects of gender were also significant, indicating that women considered all three drug types to be more harmful than did men, across all six harm rating measures. However, such findings must be interpreted in the context of the significant interaction effects between gender and drug type for all six harm ratings (see Table 2). Such interaction effects show that the gender difference in harm ratings differed according to drug. More detailed analyses showed that gender differences in overall harm ratings were substantially higher for cannabis (mean difference = 0.74, \( t = 9.68, p < 0.001 \)) than for tobacco (mean difference = 0.13, \( t = 2.12, p = 0.034 \)) and alcohol (mean difference = 0.18, \( t = 3.24, p = 0.001 \)). Similar results were found across the five specific domains.

Main effects for country also showed several significant differences in harm ratings between Norway and the UK. However, again, significant interaction effects between drug type and country for all six harm rating measures have to be taken into consideration. For instance, the interaction effect for the overall harm score showed that cannabis was rated as more harmful in Norway than the UK (\( t = 3.10, p = .002 \)), whereas both tobacco and alcohol were rated as less harmful in Norway, compared to harm ratings from the UK (\( p < .01 \)).

Finally, a series of multiple linear regression analyses were conducted to investigate the possible effects of participants’ own substance use and their religion on harm ratings. For this purpose, total tobacco, alcohol and cannabis harm ratings were used as dependent variables and country, age, gender, religion and respondents’ substance use were included as independent variables. The results are presented in Table 3. Current daily smoking was strongly and negatively associated with tobacco harm scores and a somewhat weaker association was found with previous smoking. The two highest levels of alcohol use were associated with reduced
alcohol harm ratings compared with non-use. Increasing level of cannabis use was related to reduced cannabis harm ratings. Women provided higher scores on alcohol and cannabis harm measures. Being Muslim was related to rating tobacco and cannabis as more harmful than those who reported not belonging to any religion. Types of faith, other than Christianity or Islam, were related to higher harm ratings for tobacco and alcohol. After controlling for religion and earlier cannabis use, country still significantly predicted tobacco and alcohol harm rating scores. We also compared the change in $R^2$ when including substance use in the three models shown in Table 3. Here, the increase when including cannabis (0.14) was considerably stronger than when including tobacco (0.04) or alcohol (0.03). Thus, own experiences with cannabis played a more prominent role in cannabis harm perceptions than did the use of tobacco or alcohol on perceived harm of those two substances.

Discussion

Students from the UK and Norway rated harms associated with tobacco, alcohol and cannabis in a manner that appeared to be little influenced by the legal status of the substance in question: Tobacco was regarded as most harmful with regard to physical health and dependence; alcohol was perceived as having the largest impact on injuries and violence; while cannabis was scored as most harmful with regard to mental health-effects. The total harm score of alcohol was slightly above that of cannabis. Hence, while international drug policy has been based on the premise that illegal drugs are more dangerous than legal substances, this perspective does not seem to have been supported by students in either country. There were, however, differences between students from the two countries. Somewhat surprisingly, students from the UK rated tobacco and alcohol as more harmful than those from Norway, while students from Norway perceived cannabis as more harmful than those from the UK. Gender also played a role, as women rated all three
substances as more harmful than did men, with the gender difference largest for cannabis. Finally, the students’ own use of substances reduced the harms scores for all substances, in particular with regard to cannabis harm scores, where the reduction was considerable.

Both in the UK and in Norway, students ranked alcohol as the most dangerous substance, echoing the findings from a number of different research groups’ evaluations (Room & Lubman, 2010). Yet why is this level of perceived harm not reflected in the current regulation of alcohol in European countries? In a recent paper, risks associated with psychoactive substances were divided into two groups – risks for those who themselves engage in certain behaviours and for those third persons involuntarily exposed for such risks (Rehm, Lachenmeier, & Room, 2014). The researchers showed that the morbidity and mortality risk associated with one’s own alcohol consumption clearly exceeds the risk of other comparable lifestyle factors. In addition, involuntary risks for third persons associated with alcohol also far exceed the acceptable thresholds for other comparable risks (such as those associated with, for example, traffic, bad air, contaminated water or food). Alcohol is not internationally regulated in the same manner as, for example, illegal substances, tobacco and pharmaceuticals (Bruun, Pan, & Rexed, 1975). Another reason for the lack of regulation of alcohol may be the general lack of knowledge about the risks of alcohol on various health outcomes, such as cancer, as well as the risks with regard to numerous other diseases, injuries and violence (Rehm et al., 2010). A key factor behind the lack of regulation may of course simply be associated with the perceived benefits and pleasures linked to alcohol consumption (Peele & Brodsky, 2000).

Against this background, it is interesting to see how students in both the UK and Norway—possibly to a larger degree than in previous studies – now seem to be aware of the potential harms related to alcohol consumption. These perceptions seem to have developed in tandem with reduced levels of alcohol consumption in younger cohorts all over Europe. Students from the UK
rated alcohol harms as higher than those from Norway. A reason may be found in the clearer polarisation of alcohol use in the UK sample, with larger proportions of both abstainers and high consumers. The student groups that display excessive drunken behaviour may therefore be larger in the UK, but so will the abstaining group who may perceive this behaviour as potentially harmful. Furthermore, public concern about binge drinking among young people has probably been more intense in the UK than in Norway. “Binge drinking” has been a recurring theme in the UK media (Griffin, Bengry-Howell, Hackley, Mistral, & Szmigin, 2009; Plant & Plant, 2006; Skeggs, 2005), while Norwegian media have presented only the occasional sensationalised piece.

Cannabis was rated as less dangerous than alcohol, and in this study – of university students - this may perhaps reflect an effect from new research questioning the harms of cannabis, which have received much attention in both countries and have been shared by many on social media (Maansson, 2014). However: the tendency towards decriminalisation of use and possession of cannabis in European countries (EMCDDA, 2015a); the semi-legalisation of cannabis in the Netherlands (Wouters & Korf, 2009); the drug policy reform in Portugal (Laqueur, 2015); and in particular the legalisation of cannabis in four different US states and Uruguay (Room, 2014) have also received large media coverage. The lower level of perceived harms in the UK than in Norway may possibly be related to the higher degree of normalisation of cannabis use in the UK (Measham & Shiner, 2009) than in Norway (Sandberg, 2012), as well as the considerably higher prevalence of cannabis use in the UK sample.

A main limitation of the study is related to our selected samples of students. Clearly, student samples differ from the general population, as it early was revealed that they may be more open-minded, often have less-crystallized attitudes and stronger cognitive skills (Sears, 1986). For some research questions, this limitation will not necessarily be serious, for other issues the generalization to off-campus populations may be more problematic (Hooghe, Stolle, Maheo,
& Vissers, 2010). Positive attitudes to e.g. cannabis legalization are more widespread among subgroups of urban and liberal students than in the general population (Palamar, 2014). Our samples consisted of students in social sciences who may also be assumed to be more left-leaning and critical of authorities, implying that their perceptions may not be so much influenced by the legal status of substances, than what would be the situation for e.g. students in law. Moreover, women comprised the majority of the sample, mirroring the gender-bias at universities in the UK and Norway, particularly in the social sciences and humanities. Hence, the study needs be replicated using more representative samples. While Nutt et al. (2010) weighted their criteria so as to obtain what they considered to be “a scientifically based” total harm score, our aim was not to measure “objective” or “rational” harm scores, but rather to gauge subjective perceptions of the harms associated with tobacco, alcohol and cannabis.

With this in mind, to what degree are the harm scores of the students in this study “rational”? Are they in accordance with current research-based knowledge about the possible negative effects of the three substances in question? In our opinion, the scores are broadly in line with experts' ratings. For example, tobacco and alcohol are rated as two of the most critical factors for the global burden of disease and mortality (Lim et al., 2012). The scores for alcohol, injuries and violence also correspond well with numerous research reports (Taylor et al., 2010). Students at both universities rated cannabis as the most harmful substance with regard to mental health problems. Even though the often-cited association between cannabis use and schizophrenia (Andreasson, Engstrom, Allebeck, & Rydberg, 1987) may be less certain than suggested (Hickman et al., 2009), there is little doubt than cannabis may lead to brief psychotic episodes and cognitive impairment (Degenhardt & Hall, 2012).

Women reported higher scores in all rankings than men. This finding echoes both previous research showing that men are more prone to risky substance use behaviours than
women (E Kuntsche, Knibbe, Gmel, & Engels, 2005), and men’s lower perceived level of vulnerability with regard to risk-taking (Anderson & Galinsky, 2006). Typically, women are also more in favour of restrictive drug and alcohol policies than men (Moskalewicz, Wieczorek, Karlsson, & Osterberg, 2013).

**Conclusion**

Students from the UK and Norway rated alcohol as slightly more harmful than cannabis. Their ratings are in accordance with reports from research committees over the last couple of decades, but in contrast to the ideas behind the international conventions regulating narcotic drugs. Even though our samples were highly selected, the findings may be indicative of a decreasing legitimacy of the policy relating to narcotic drugs. There are numerous other indications that the international political consensus in this area is fracturing, partly fuelled by the fact that the key driver behind these regulations – the USA – is gradually legalising cannabis (Bewley-Taylor, 2012). Our study gives additional support to such evidence. At the same time, one should note the students’ awareness of the possible harms related to the use of alcohol – which may imply that a restrictive alcohol policy in the future may come to have support in younger cohorts.
