(Received 23 June 2014; published 9 March 2015)

The Gaussian kinematic formula (GKF) [R. J. Adler and J. E. Taylor, Random Fields and Geometry (Springer, New York, 2007),] is an extremely powerful tool allowing for explicit analytic predictions of expected values of Minkowski functionals under realistic experimental conditions for cosmological data collections. In this paper, we implement Minkowski functionals on multipoles and needlet components of CMB fields, thus allowing a better control of cosmic variance and extraction of information on both harmonic and real domains; we then exploit the GKF to provide their expected values on spherical maps, in the presence of arbitrary sky masks, and under non-Gaussian circumstances. All our results are validated by numerical experiments, which show a perfect agreement between theoretical predictions and Monte Carlo simulations.

I. INTRODUCTION

A general trend in modern cosmological research is the implementation of more and more sophisticated statistical tools to perform data analysis. Indeed, well-known cosmological data have reached over the last decade an unprecedented accuracy, so that it has become customary to speak about a golden era for cosmology, featuring a data deluge from many satellite- and ground-based experiments. As the data grow in size and precision, more and more detailed questions can be addressed, and exploiting techniques at the frontier of statistical and mathematical research becomes mandatory to warrant a full exploration of the available evidence.

Among these techniques, stochastic geometry tools have now become very well established, especially in the field of cosmic microwave background radiation experiments. In this area, one of the most popular geometric tools for data analysis is certainly the so-called Minkowski functionals (MFs), which have been extensively exploited as tools to search for non-Gaussianities, anisotropies, asymmetries and other features of CMB data. The use of MFs in cosmology goes back at least to [1,2]; a complete bibliography would certainly include hundreds of entries, so we refer only to the earlier works by [3–11] and to the more recent ones by [12–17].

As is well known, on the plane there are three Minkowski functionals $M_0$, $M_1$, $M_2$ which can be taken to represent, respectively, the area, the boundary length and the Euler-Poincaré characteristic (number of connected components minus holes) of any given region. To characterize the behavior of data from a random field $T(x)$, say it has then become customary to consider flat-sky approximations and to focus on the excursion sets

$$A_u(T) := \{ x : T(x) \geq u \},$$

e.g. the regions of the plane where the value of $T$ exceeds the threshold $u$; the corresponding functionals $M_i(A_u(T))$, $i = 0, 1, 2$, can then be computed for real data with a number of accurate and numerically efficient packages. The expected values of the Minkowski functionals in the planar case and under Gaussianity is analytically known to the literature since the work of Adler in the early 1980s ([18], see also [1]), and these predictions can be compared to values on observed data to implement a number of statistical tests (see for instance [17] and the references therein).

In the last decade, major progress has occurred in the mathematical understanding of the geometry of random fields, namely the discovery of the Gaussian kinematic formula (GKF) by Taylor and Adler (see [19–23]).

As we shall discuss in the next section, the GKF allows a simple computation of the expected values for Lipschitz-Killing curvatures (equivalent to Minkowski functionals; see below) under an impressive variety of extremely different circumstances, covering arbitrary manifolds with and without masked regions and a broad class of non-Gaussian models. These expected values take extremely neat and intuitive forms, and can be immediately compared to simulations and observed data. One of our purposes in this paper is to exploit these recent results to develop a
number of analytic predictions on functionals tailored to test non-Gaussianities and asymmetries on CMB data. More precisely, in this paper we aim at the implementation of Minkowski functionals/Lipschitz-Killing curvatures on the multipole and needlet components of observed data. To be more explicit, we start from the decomposition of an observed spherical (e.g., CMB) map into harmonics as

$$T(x) = \sum_{\ell=1}^{\ell_{\text{max}}} \sum_{m=-\ell}^{\ell} a_{\ell m} Y_{\ell m}(x) = \sum_{\ell=1}^{\ell_{\text{max}}} T_\ell(x).$$  \hfill (2)

It is well known that the decomposition (2) is only feasible for unmasked (full-sky) data, a condition which is usually considered very difficult to meet for CMB experiments (see, however, the recent full-sky maps produced by [24]). To handle masked regions, it has hence become very popular to introduce various forms of spherical wavelets, which enjoy much better localization properties than spherical harmonics in the real domain, and are therefore much less affected by sky cuts. In this paper, we shall focus in particular on the needlet system, which is defined by the filter

$$\psi_{jk}(x) = \sum_{\ell, m} b_\ell \left( \frac{\ell}{B} \right) \tilde{Y}_{\ell m}(\xi_{jk}) Y_{\ell m}(x),$$  \hfill (3)

where \{\xi_{jk}\} denotes a grid of points on the sphere (such as HealPix centers at a given resolution; see [25]), \(B > 1\) is some fixed bandwidth parameter and the weight function \(b_\ell(\xi)\) satisfies three conditions, namely (a) it is compactly supported in the interval \((B^{-1}, B)\); (b) it is smooth; (c) the partition of unity property holds, e.g., \(\sum_{\ell} b_\ell^2(\xi) = 1\) for all \(\xi\). Needlets have been shown to enjoy very good localization properties in the real domain; needlet coefficients are given by the projection

$$\beta_{jk} = \int_{S^2} T(x) \psi_{jk}(x) dx = \sum_{\ell-B^{-1}}^{\ell+B^{-1}} \sum_{m} b_\ell \left( \frac{\ell}{B} \right) a_{\ell m} Y_{\ell m}(\xi_{jk}),$$  \hfill (4)

and they allow for the reconstruction formula

$$T(x) = \sum_{j=1}^{j_{\text{max}}} \sum_{k} \beta_{jk} \psi_{jk}(x) = \sum_{j=1}^{j_{\text{max}}} \beta_{j}(x),$$  \hfill (5)

$$\beta_{j}(x) = \sum_{k} \beta_{jk} \psi_{jk}(x) = \sum_{\ell-B^{-1}}^{\ell+B^{-1}} \sum_{m} b_\ell^2 \left( \frac{\ell}{B} \right) a_{\ell m} Y_{\ell m}(x);$$  \hfill (6)

see [26], [27], [28], [29] for further discussions and applications to some CMB data analysis issues.

Our aim is to apply Minkowski functionals on both the field components \(\{T_\ell(x), \beta_j(x)\}\) rather than on the original map. This form of harmonic/needlet space geometric analysis has a number of advantages that it is immediate to see (see also [30] for some mathematical results in this area). For instance, any deviation from the analytic predictions can be exactly localized on the real and harmonic space, thus allowing for a much neater interpretation; indeed, a scale-by-scale probe of asymmetries and relevant features becomes feasible. Also, while the behavior of MFs on standard CMB maps is unavoidably affected by cosmic variance, the effect is much smaller for MFs evaluated on the highest needlet scales: it becomes possible to discriminate quite clearly cosmic variance effects from effective deviations. Indeed, the variances of these Minkowski functionals converge to zero as the frequency increases, so that fluctuations around expected values become negligible on small scales, assuming the null assumptions hold. This allows for a very precise investigation of asymmetries and anisotropies; in a future work we shall provide some exact computations on the variances of these functionals and corresponding aggregated statistics.

The plan of the paper is as follows: in Sec. II, we illustrate some background material on the GKF and we present its application to needlet and multipole components under the simplest conditions, e.g., full-sky Gaussian maps. In Sec. III we present analytic results for some non-Gaussian fields arising when testing for asymmetries and directional variations in non-Gaussianity, while Sec. IV is devoted to the formulas for the exact expected values in the presence of masked regions. In Sec. V we present our detailed numerical studies, and we illustrate our software which allows for numerical corrections of expected values in the presence of masked regions of any form. Section VI draws some conclusions and presents directions for future work.

II. THE GAUSSIAN KINEMATIC FORMULA

A. The general case

For cosmological applications, it would seem sufficient to restrict our attention to random fields or observational data on the unit sphere \(S^2\); however we shall show below that presenting results in a more general setting does yield some practical advantages, especially when dealing with masked data. Indeed, the GKF holds in much greater generality, and it can certainly be exploited for other experimental setups, for instance three-dimensional observations (viewed as data on the three-dimensional ball—this and other cases will be the object of future works).

On the sphere, the excursion sets \(A_u(f)\) of a given (possibly random) function \(f\) are defined as

$$A_u(f) := \{x \in S^2: f(x) \geq u\}.$$  \hfill (7)

Of course, in the limit where we take \(u = -\infty\), we have that \(A_u(f) = S^2\).
The Lipschitz-Killing curvatures (LKCs) of these excursion sets, written
\[ \mathcal{L}_0(A_u(f)), \mathcal{L}_1(A_u(f)), \mathcal{L}_2(A_u(f)) \] (8)
are defined as
(i) \( \mathcal{L}_0(A_u(f)) \) is the Euler-Poincaré characteristic, e.g. in two dimensions the number of connected regions minus the number of holes, and in three dimensions the number of connected components minus the number of "handles" plus the number of holes; see [22] for more discussion. This corresponds (up to a constant factor; see Appendix) to the third Minkowski functional, or two minus the genus; we recall that the Euler-Poincaré characteristic of the full sphere is equal to 2.
(ii) \( \mathcal{L}_1(A_u(f)) \) is half the boundary length of the excursion regions, e.g. the second Minkowski functional up to a factor 2. For the full sphere, the boundary length is clearly zero.
(iii) \( \mathcal{L}_2(A_u(f)) \) is the area of the excursion regions, e.g. the first Minkowski functional. For the full sphere, one obviously gets 4π.

For more general manifolds, the definitions are given in the Appendix. We shall focus on random fields that have zero mean, unit variance and are isotropic. These assumptions can be easily abandoned, entailing just a more complex notation; of course, zero mean and unit variance can be enforced by normalization (incidentally, it is well known that needlet and multipole component random fields always have zero mean under isotropy). Let us now introduce some more notation; consider the family of functions \( \rho_i(u) \) given by
\[ \rho_i(u) = (2\pi)^{-i+1/2}H_{i-1}(u)e^{-u^2/2}, \] (9)
where \( H_k(u) \) denotes standard Hermite polynomials, e.g.,
\[ H_0(u) = 1, \quad H_1(u) = u, \quad H_2(u) = u^2 - 1; \] (10)
we adopt the standard convention that
\[ H_{-1}(u) = \sqrt{2\pi}(1 - \Phi(u))e^{u^2/2}, \] (11)
where \( \Phi(u) \) is the standard Gaussian cumulative distribution function, so that
\[ \rho_0(u) = (2\pi)^{-1/2}\sqrt{2\pi}(1 - \Phi(u))e^{u^2/2}e^{-u^2/2} = (1 - \Phi(u)) \] (12)
\[ \rho_1(u) = \frac{1}{2\pi}e^{-u^2/2}, \quad \rho_2(u) = \frac{1}{\sqrt{(2\pi)^3}}ue^{-u^2/2}. \] (13)

It is interesting to note that \( \frac{1}{\sqrt{2\pi}}H_k(u)e^{-u^2/2} \) gives \((-1)^k \) times the \( k \)th derivative of a standard Gaussian density, \( k \geq 0 \). In the mathematical literature this component is written as \( \mathcal{M}_k([u, \infty)) = \frac{1}{\sqrt{2\pi}}H_k(u)e^{-u^2/2} \) and labeled a Gaussian Minkowski functional. Up to a constant factor, \( \rho_i \)'s are known in the cosmological community as the normalized Minkowski functionals, and are commonly denoted as \( v_k \).

The next ingredient we shall need are the so-called "flag" coefficients, which are given by
\[ \left[ \begin{array}{c} i + 1 \\ l \end{array} \right] = \left( \begin{array}{c} i + 1 \\ l \end{array} \right) \frac{\omega_{i+l}}{\omega_i \omega_l}, \quad \text{for} \quad \omega_i = \frac{\pi^{i/2}}{\Gamma(\frac{i}{2}+1)}, \] (14)
so that \( \omega_i \) represents the area of the \( i \)-dimensional unit ball, \( \omega_1 = 2, \omega_2 = \pi, \omega_3 = \frac{4}{3}\pi \). Finally, we shall introduce a parameter \( \lambda \), which represents the variance of any gradient component at the origin; equivalently \( \lambda \) is simply given by the second derivative of the covariance function at the origin.

Under these circumstances, for random fields defined on general manifolds \( D \) the GKF is given by the following, extremely elegant expression (see for instance Theorem 13.2.1 [23]):
\[ \lambda^{i/2}E[L_k(A_u(T(x), D)) = \sum_{l=0}^{\text{dim}(D)-i} \left[ \begin{array}{c} i + l \\ l \end{array} \right] \lambda^{l/2}\rho_l(u)L_{i+l}(D). \] (15)

This expression may seem unnecessarily complicated, given that in this paper we shall focus only on spherical random fields; however this generality will indeed be required below, when we shall consider masked data (which we will see as data sampled from a different manifold, i.e. the sphere with sky cuts). Before we proceed, however, it is important to stress some crucial features of the result given in (15). Indeed, it must be noted that the expression on the right-hand side of (15) allows for a full decoupling of the expected value on the left-hand side into components which are completely independent: the LKCs of the original manifold \( L_k(D) \), which depend on the manifold \( D \) but not on the threshold value \( u \) nor on the covariance structure of the field we investigate; and the functions \( \rho_i(u) \), which depend only on the chosen threshold level \( u \), and are independent from the structure of the field and from the properties of the manifold \( D \). This will allow for enormous computational advantages in the sections to follow: for instance, covering the presence of sky cuts will entail a new computation for the values of \( L_{i+l}(D) \) this computation can be done only once for a given mask, and is independent of the threshold levels or the correlation structure of the field. Likewise, moving to non-Gaussian circumstances will entail a corresponding replacement of the functions \( \rho_i(u) \), but no new computations will be required on correlation structure or to handle gaps. A particularly neat interpretation can be provided, by simply grouping together the terms \( \lambda^{i/2} \) and \( L_{i+l}(D) \), to obtain
in mathematical terms, \( \mathcal{L}_q(D) \) is usually described as a LKC computed with a metric induced by the random field \( T \), e.g. a manifold which has been rescaled by multiplication times \( \sqrt{\lambda} \), the square root of the second derivative of its covariance function at the origin. All these notions may seem somewhat abstract, but they yield very simple analytic expressions in the case of spherical random fields \( D = S^2 \), to which we now turn our attention.

### B. The spherical case

An example of excursion regions of the CMB for different threshold levels is given by Fig. 1.

The application of the previous general results to the sphere (without masks) basically provides expressions which are already known to the CMB literature, up to some correction terms. Indeed, in the case of a single multipole \( T_\ell(x) = \sum_m a_m Y_{\ell m}(x) \), normalized to have variance 1 (e.g., divided by \( \sqrt{\Gamma_\ell} \), where \( \Gamma_\ell = 2\ell + 1 C_\ell \)), \( \lambda \) is easily seen to be (see [30])

\[
\lambda_\ell = \frac{\ell (\ell + 1)}{2},
\]

while for the needlet field \( \beta_j(x) \), again normalizing the variance [which is given by \( \sum_j b^4(\gamma_j) C_\ell \frac{2\ell + 1}{4\pi} \)] we have

\[
\frac{\sum_j b^4(\gamma_j) C_\ell \frac{2\ell + 1}{4\pi}}{\sum_j b^4(\gamma_j) C_\ell \frac{2\ell + 1}{4\pi}} = \frac{\sum_j b^4(\gamma_j) \Gamma_\ell \lambda_\ell}{\sum_j b^4(\gamma_j) \Gamma_\ell};
\]

note that the numerator is just the variance of the derivative map before normalization.

Finally, as mentioned earlier the Lipschitz-Killing curvatures take an extremely simple form on the full sphere: it is indeed well known that the Euler-Poincaré characteristic is identically equal to 2, the boundary length is of course zero (the sphere has no boundary), and the area is simply \( 4\pi \), i.e.

\[
\mathcal{L}_0(S^2) = 2, \quad \mathcal{L}_1(S^2) = 0, \quad \mathcal{L}_2(S^2) = 4\pi.
\]

Also in this setting

\[
\begin{bmatrix} 1 \\ 0 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \end{bmatrix} = \begin{bmatrix} 2 \\ 0 \end{bmatrix} = \begin{bmatrix} 2 \\ 1 \end{bmatrix} = 1, \quad \begin{bmatrix} 2 \\ 1 \end{bmatrix} = \frac{\pi}{2}.
\]

After making all these replacements in (15), we thus obtain general expressions for expected values in the case of multipole and needlet components which are given in the following two subsections.

### C. Multipole fields

In the case of a single multipole \( T_\ell(x) \), normalized to have variance 1, the GKF yields immediately (compare [30], Corollary 5)

\[
\mathbb{E} \mathcal{L}_0(A_u(T_\ell(.), S^2)) = 2\{1 - \Phi(u)\} + \lambda_\ell \frac{ue^{-u^2/2}}{\sqrt{(2\pi)^3}} 4\pi;
\]

\[
\mathbb{E} \mathcal{L}_1(A_u(T_\ell(.), S^2)) = \frac{\pi}{2} \lambda_\ell^{1/2} e^{-u^2/2} 4\pi = \pi \lambda_\ell^{1/2} e^{-u^2/2};
\]

and

\[
\mathbb{E} \mathcal{L}_2(A_u(T_\ell(.), S^2)) = 4\pi \times \{1 - \Phi(u)\}.
\]
D. Needlet fields

The expected value of the Euler-Poincaré characteristic is given by (see [30], Lemma 3)

\[ \mathbb{E}L_0(A_u(\beta_j(x), S^2)) = 2\{1 - \Phi(u)\} + \frac{\sum b^4(\ell \frac{f}{2}) \Gamma_{\ell} \lambda \epsilon \ u e^{-u^2/2}}{\sum b^4(\ell \frac{f}{2}) \Gamma_{\ell}} \sqrt{(2\pi)^3} 4\pi \]  

(24)

the second Lipschitz-Killing curvature (e.g., half the boundary length) has expected value

\[ \mathbb{E}L_1(A_u(\beta_j(x), S^2)) = \pi \left\{ \frac{\sum b^4(\ell \frac{f}{2}) \Gamma_{\ell} \lambda \epsilon}{\sum b^4(\ell \frac{f}{2}) \Gamma_{\ell}} \right\}^{1/2} e^{-u^2/2}. \]

(25)

Finally, the third Lipschitz-Killing curvature (e.g., the area of the excursion region) has the following expected value, which is the simplest to check:

\[ \mathbb{E}L_2(A_u(\beta_j(x), S^2)) = 4\pi \{1 - \Phi(u)\}. \]

(26)

The expressions (22), (23), (25), (26) match those that would be obtained by replacing the angular power spectrum of a needlet field/multipole component in the standard expressions for expected values of Minkowski functionals, as given for instance in [17], pp. 10–11. On the other hand, on the right-hand side of (21), (24) there is an extra term that fully takes into account the spherical geometry: this term is missing when the result is derived by resorting to a flat-sky approximation. All these results are perfectly matched by the simulations presented below; we can hence move to consider non-Gaussian fields and masked regions, as done in the following sections.

III. NON-GAUSSIAN EXPECTED VALUES

Before we go ahead to discuss the analytic results, it is important to motivate the class of non-Gaussian fields we wish to consider.

A major thread of last decade’s research in the field of CMB has been related to the investigation of possible asymmetries and directional variations in the observed data. Seminal papers in this area were provided by the authors of [31–39] working on the early WMAP data release, but the field is still now very active and hotly debated; see [17] and the references therein. In this framework, it is well known that needlet coefficients or fields can provide unbiased estimates for smoothed versions of the angular power spectrum, the bispectrum or any higher-order statistics; these estimates are spatially localized, so they can be immediately used to test for instance power asymmetries, an idea first developed in [40], [41].

More explicitly, consider the squared field \( \beta_j^2(x) \); from the localization properties of the needlet frame; it is obvious that the value of \( \beta_j(x) \) is only determined by CMB radiation in a small neighborhood around \( x \), while we have moreover

\[ \mathbb{E} \beta_j^2(x) = \mathbb{E} \left\{ \sum_{\ell = B_{\ell}}^{B_{\ell+1}} b^2 \left( \frac{\ell}{B_i} \right) T_{\ell}(x) \right\}^2 = \sum_{\ell = B_{\ell}}^{B_{\ell+1}} b^4 \left( \frac{\ell}{B_i} \right) \Gamma_{\ell}; \]

(27)

e.g., the squared coefficients provide natural unbiased estimates for a binned angular power spectrum. Along the same lines, the cube of these coefficients provides an unbiased, local estimator of the binned bispectrum, which is a natural candidate to search for directional variations in non-Gaussianity:

\[ \mathbb{E} \beta_j^3(x) = \mathbb{E} \left\{ \sum_{\ell_1, \ell_2, \ell_3} b^2 \left( \frac{\ell_1}{B_i} \right) b^2 \left( \frac{\ell_2}{B_i} \right) b^2 \left( \frac{\ell_3}{B_i} \right) \Gamma_{\ell_1} \Gamma_{\ell_2} \Gamma_{\ell_3} \right\} \]

where \( b_{\ell_1, \ell_2, \ell_3} \) denotes as usual the reduced bispectrum and the Wigner’s 3j symbols have appeared in the last equation; see [42], [29] for more references and details. In the remaining part of this section we shall provide the analytic expectation also for the Minkowski functionals/ Lipschitz-Killing curvatures of these cubic statistics. These results can be rigorously derived by an application of a more general form of the GKF, which is given in the Appendix. However, from a more heuristic point of view their derivation can be provided from a very simple argument. Indeed, consider for instance a quadratic transformed field \( W = T^2 \); the excursion region of the field \( W \) over a level \( u \) is easily seen to be given by the region where \( T > \sqrt{u} \), plus the region where \( T < -\sqrt{u} \). In view of the
decoupling we reported below, the expected values of the LKCs for the quadratic case turn out to be just the sum of the corresponding Gaussian results over these two regions. Likewise, for the cubic case $W = T^3$ the excursion region will be obtained by simply considering the excursion sets of $T$ over the level $\sqrt{u}$. This simple heuristic would not work in more complicated circumstances where the GKF still provides exact solutions, but it is enough to justify the results we report below.

A. The quadratic case

We start from the case where we square the needlet field, as if we were interested in local estimates of the power spectrum. As usual, we normalize the starting Gaussian field to have unit variance, and we are hence focusing on the square field defined by

$$\beta_{j,2}(x) = \frac{\beta_j^2(x)}{\text{Var}(\beta_j(x))} = \frac{\beta_j^2(x)}{\sum \ell b_4(\ell) \Gamma_\ell}.$$  \hspace{1cm} (28)

As motivated by the previous heuristic, or as derived more rigorously by the general GKF (see Appendix), we have the following analytic predictions ([30], pp. 13–14):

(i) For the expected value of the Euler characteristic

$$\mathbb{E}L_0(A_u) = 4(1 - \Phi(\sqrt{u}))$$

$$+ 4 \sum_\ell b_4(\ell) \Gamma_\ell \lambda_\ell e^{-u/2} \frac{1}{\sqrt{2\pi \sqrt{u}}}.$$ \hspace{1cm} (29)

(ii) For the second Lipschitz-Killing curvature (i.e., half of the boundary length)

$$\mathbb{E}L_1(A_u) = 2\pi \left( \frac{\sum_\ell b_4(\ell) \Gamma_\ell \lambda_\ell \Gamma_\ell}{\sum_\ell b_4(\ell) \Gamma_\ell} \right)^{1/2} e^{-u/2};$$ \hspace{1cm} (30)

(iii) Finally for the area of excursion regions

$$\mathbb{E}L_2(A_u) = 4\pi \times 2(1 - \Phi(\sqrt{u})).$$ \hspace{1cm} (31)

The results for the square of normalized multipole components $[T_j^2/\mathbb{E}(T_j^2)]$ are entirely analogous, and indeed even simpler to state:

![FIG. 2](color online). Multipole space Gaussian case: analytical (red) vs simulations (black and grey). The legend shows the multipoles at which the LKCs are evaluated. Grey shades are 68%, 95% and 99% percentiles estimated from 100 simulations. The red analytical curve is not visible in the print version but it is within the 68% confidence bound.
(i) For the expected value of the Euler characteristic
\[ \mathbb{E} \mathcal{L}_0(A_u) = 4(1 - \Phi(\sqrt{u})) + 4\lambda e^{-u/2} \sqrt{2\pi} \sqrt{u}; \] (32)

(ii) For the second Lipschitz-Killing curvature (i.e., half of the boundary length)
\[ \mathbb{E} \mathcal{L}_1(A_u) = 2\pi (\lambda e)^{1/2} e^{-u/2}; \] (33)

(iii) Finally for the area of excursion regions
\[ \mathbb{E} \mathcal{L}_2(A_u) = 4\pi \times 2(1 - \Phi(\sqrt{u})). \] (34)

**B. The cubic case \( \beta^3_j(x) \)**

Cubic transformations are the natural candidates to search for anisotropies in the bispectrum we simply take the cube of the needlet fields. The analytic predictions are then as follows (see also [30], p. 14 and the Appendix for details):

(i) The expected value of the Euler characteristic is given by
\[ \mathbb{E} \mathcal{L}_0(A_u(\beta^3_j(x); S^2)) = 2(1 - \Phi(\sqrt{u}))(1 - \Phi(\sqrt{u})) \]
\[ + 2 \sum e^{b_4(\frac{\beta_j}{b_4})} \Gamma \lambda e^{-(\sqrt{u})^2/2} \frac{1}{\sqrt{2\pi}} \sqrt{u}; \] (35)

(ii) The expected value for half the boundary length is
\[ \mathbb{E} \mathcal{L}_1(A_u(\beta^3_j(x); S^2)) = \pi \left( \sum e^{b_4(\frac{\beta_j}{b_4})} \Gamma \lambda e^{-(\sqrt{u})^2/2} \right)^{1/2}; \] (36)

(iii) Finally, the expected value of the area of excursion regions is
\[ \mathbb{E} \mathcal{L}_2(A_u(\beta^3_j(x); S^2)) = 4\pi (1 - \Phi(\sqrt{u})). \] (37)

**FIG. 3 (color online).** Needlet space Gaussian case: analytical (red) vs simulations (black and grey). The needlet parameters are \( B = 1.5 \), \( j = 10, 12, 14 \). The central multipoles of the corresponding needlet filter are given in the legend. Grey shades are 68\%, 95\% and 99\% percentiles estimated from 100 simulations. The red analytical curve is not visible in the print version but it is within the 68\% confidence bound.
The corresponding values for the cube of normalized multipole components are given by

(i) The expected value of the Euler characteristic is given by

$$E_{\mathcal{L}_0}(A_u(\beta^3_j(x); S^2)) = 2(1 - \Phi(\sqrt{u})) + 2\lambda_2 e^{-\sqrt{u}^2/2\sqrt{2\pi}}.$$  (38)

(ii) The expected value for half the boundary length is

$$E_{\mathcal{L}_1}(A_u(\beta^3_j(x); S^2)) = \pi \{ \lambda_2 \}^{1/2} e^{-\sqrt{u}^2/2};$$  (39)

(iii) Finally, the expected value of the area of excursion regions is

$$E_{\mathcal{L}_2}(A_u(\beta^3_j(x); S^2)) = 4\pi(1 - \Phi(\sqrt{u})).$$  (40)

It should be noted that the area measure is completely insensitive to the behavior of the correlation structure, and therefore takes the same values in the needlet and multipole cases.

IV. MASKED REGIONS

In the analysis of data collected from experiments with masked regions, as it is basically always the case in cosmology, the full power of the GKF emerges most clearly. Let us denote by $M = S^2 \setminus G$ the sphere to which the masked regions (for instance, the galactic cut) have been subtracted; it is then sufficient to replace the LKCs $L_{i+l}(M)$ to $L_{i+l}(S^2)$ in (15), (19) to obtain the desired result. At first sight, however, this may appear as a very difficult task: how can we replace the simple values provided in (19) with the LKC for a masked region, possibly with a highly complicated structure including many removed point sources and other foreground regions with complex shapes? For the area measure $L_2(S^2 \setminus G)$ the computation could be trivial (by simply adjusting the sky

FIG. 4 (color online). Multipole space non-Gaussian quadratic case: analytical (red) vs simulations (black and grey). The legend shows the multipoles at which the LKCs are evaluated. Grey shades are 68%, 95% and 99% percentiles estimated from 100 simulations. The red analytical curve is not visible in the print version but it is within the 68% confidence bound.
fraction), but for the boundary length $L_1(S^2 \setminus G)$ and the Euler-Poincaré characteristic $L_0(S^2 \setminus G)$ this problem may seem quite hard, especially when a huge number of removed point sources is given.

A very simple solution can however be provided by exploiting one more time the GKF, following an idea discussed in [22], Chapter 5.4. In fact, for any given mask one can choose a simple isotropic random field with known angular power spectrum, and from this one may evaluate by Monte Carlo simulations the realized values of LKC of excursion sets at some fixed levels of threshold values $u$. These realized values can then be compared with the analytic predictions; for a given input angular power spectrum, these are fully known, up to some fixed parameters representing the LKCs $L_i(S^2 \setminus G)$. These parameters can then be estimated once for all by simple least square regression, and used as an input to derive analytic predictions for a given mask. These predictions would hold for arbitrary threshold values $u$ and irrespective of the covariance structure, the frequency or scales $j, \ell$ considered, the Gaussian or non-Gaussian circumstances.

In summary, the following multistep procedure is advocated:

1. Fix a simple power spectrum $C_l$, for instance with $\ell_{\text{max}} = 10$, and generate Gaussian maps out of it.
2. Fix a limited number of threshold values $u$ and perform a Monte Carlo evaluation of the LKCs $L_i(S^2 \setminus G)$, $i = 0, 1, 2$ in Eq. (15).
3. Use least square regression to estimate $L_i(S^2 \setminus G)$, $i = 0, 1, 2$ in Eq. (15).
4. Use the estimates obtained in point 3 as an input for Eq. (15) for any arbitrary power spectrum (for instance, multipole or needlet components on realizations of a ΛCDM model, under Gaussian and non-Gaussian circumstances).

We believe that this routine illustrates very vividly the advantages of the decoupling between domain manifold, covariance structure and threshold value achieved by the GKF (15). The resulting predictions are indeed extremely accurate, as illustrated in the following section.

V. NUMERICAL RESULTS

In this section we describe the comparison of the analytical results outlined in the previous sections to the
corresponding results from simulations. In all cases we generated 100 map realizations of an input power spectrum using the HEALpix [25] package. We estimated LKCs from each simulation and compared their mean with the analytical results. We found an excellent agreement in all the cases that we investigated; more precisely, not only are the estimated curves always well within the 68% confidence interval (C.L.), but actually as shown below they are for practical purposes basically indistinguishable from the theoretical predictions even with a relatively low number of Monte Carlo simulations.

A. Simulations and algorithm

We used HEALpix synfast to simulate a map from a given power spectrum; the choice of this power spectrum has no influence on the results we shall provide. The procedures to obtain the single multipole or needlet maps are standard and can be described as follows: first we harmonic transform the simulated maps using anafast; then to obtain \( T_\ell(x) \) or \( \beta_j(x) \) maps, we simply take the appropriate inverse transform across the relevant multipoles, in the case of needlets inserting also the squared needlet filter \( b^2(\cdot) \). The multipole/needlet maps are then normalized by their root mean square, which is computed analytically using the input power spectrum; see below.

From these normalized multipole/needlet maps we then computed the three Minkowski functionals, which as argued earlier are equivalent to the LKCs up to constant factors. This implementation is achieved by exploiting the algorithms described in [43]. In short, these algorithms can be described as follows: the area, i.e. the first MF, is computed by evaluating the number of pixels above a certain threshold. The length, the second MF, is computed by tracing isocontour lines in pixel space. For a sufficiently high-resolution map, pixels around isocontour lines have different signs relative to the contour line, after normalizing the lines to zero. To measure the length of these lines, sets of four pixels are compared; when at least two of them have different signs, the locations where the contour line enters and exits these sets of pixels are determined and the length is iteratively calculated by standard dot product. The Euler-Poincaré, the third MF, is computed by means of its characterizations through Morse theory; more explicitly, critical points are determined as the pixels where the gradient vanishes. The Hessian matrices around these critical points are computed, and their so-called indexes

![Graphs of multipole space non-Gaussian cubic case: analytical (red) vs simulations (black and grey).](image)

FIG. 6 (color online). Multipole space non-Gaussian cubic case: analytical (red) vs simulations (black and grey). The legend shows the multipoles at which the LKCs are evaluated. Grey shades are 68%, 95% and 99% percentiles estimated from 100 simulations. The red analytical curve is not visible in the print version but it is within the 68% confidence bound.
(i.e., the sign of their determinant, or the product of their eigenvalues) are evaluated. Positive indexes correspond to extrema (minima plus maxima), negative indexes to saddles; in two dimensions, the Euler-Poincaré characteristic is simply obtained as the difference between the number of extrema and the number of saddles.

Our detailed investigation using different algorithms to compute the Euler-Poincaré characteristic showed that for
a map defined at a given $N_{\text{side}}$, the maximum multipole for which a percent numerical accuracy can be obtained is
\[ \ell_{\text{max}} \sim N_{\text{side}}/3. \]
Moreover, since a polynomial transformation of a band limited map increases the bandwidth accordingly, in the following we show only results for multipoles $\ell < 500$. While it would be possible to cover larger values, we do not believe this is essential for our purpose in this paper.

**B. On normalization issues**

As mentioned, all the maps we used to estimate the LKCs are normalized to have unit variance; hence the threshold levels $-2, -1, 0, 1, 2, \ldots$ are given in terms of the standard deviation. It should be noted that at low multipoles, the sample variance need not be close to the population value, due to cosmic variance effect. As a result of this, normalizing maps by their respective sample root mean square would lead to incorrect estimates of the mean and variance of LKCs. We also stress that population variances can trivially be derived from any given power spectrum; for instance, as recalled earlier the variance of a needlet map at frequency $j$ is given by

\[ \sigma^2(\beta_j) = \sum_{\ell=0}^{Bj-1} b^4 \frac{(\ell+1)C_\ell}{4\pi}. \]  

(41)

In the case where the input spectra are not known, one should use the best-fit power spectra from the map to compute the normalization factor.

**C. Code validation**

To understand the accuracy of our code in estimating the MFs, in particular in measuring the length of isocontour lines, we used some test functions for which the relevant quantities are analytically known. For instance one such function we used is

\[ f(\theta, \phi) = \sin(n\theta), \]  

(42)

for which the length of isocontour lines at level zero is given by $2\pi \sum_{h=1}^{n-1} \sin(\frac{h\pi}{n})$; the results from our code are consistent with these theoretical values to better than 0.001%. Of course, the accuracy may degrade for highly oscillatory functions, but we believe this test provides a good validation to the entire pipeline and shows that the algorithms we employed are very reliable.

FIG. 9 (color online). Multipole space Gaussian masked case: analytical (red—full sky; blue—mask corrected) vs simulations (black and grey). The legend shows the multipoles at which the LKCs are evaluated. Grey shades are 68%, 95% and 99% percentiles estimated from 100 simulations. The red analytical curve is not visible in the print version but it is within the 68% confidence bound.
D. Results: Gaussian fields

In Fig. 2 we compare the multipole space analytical results (red curve) given in Sec. II B with those of the simulations (black curve—mean of the simulations). The 68%, 95% and 99% C.L.’s are shown from dark to light grey bounds. From the left to right panels, the plots show the results corresponding to multipoles $\ell = 5, 50, 105$. We stress that our fit is extremely accurate, even at very low multipole values where the flat-sky approximation which is usually adopted cannot be expected to hold. We also note the improved concentration around the expected values at higher multipoles; indeed, the same behavior of these variances can be predicted analytically, but we delay these results for future work.

Likewise, Fig. 3 shows analogous results in needlet space; the colors for different curves have the same meaning as described above. The displayed results cover the frequencies $j = 10, 12, 14$ which for $B = 1.5$ correspond to multipoles in the order of 60, 130, 200. These results are even more accurate than in the multipole case; in particular the decay of cosmic variance is faster.

E. Results: Non-Gaussian fields

As described before, our non-Gaussian maps are constructed by taking a power transform of a Gaussian input. We also argued earlier in Sec. III that the quadratic power transform seems useful to investigate power spectrum asymmetries, while the cubic transform provides a natural probe of possible directional variations in non-Gaussianity.

In Figs. 4 and 5 we compare the analytical results for the quadratic case in multipole and needlet space with those from the simulations, respectively. As described above the red curves are for analytical predictions, while the black and grey ones are for simulations.

Similarly, in Figs. 6 and 7 we show analytical vs simulation results for the cubic non-Gaussian case in multipole and needlet space, respectively. The fit between predicted values and simulations is again extremely good.

F. Results: Masked sky case

 Probably the main contribution in this paper relates to the possibility of using the GKF to handle analytically the effect of sky cuts on Minkowski functionals; see the...
discussion in Sec. IV. As a numerical validation of the analytical results for the expected values of LKCs in the presence of a sky mask, here we use the realistic Planck official sky mask, which is formed as a union of different foreground separation method confidence masks together with point source masks. The cut regions are shown in Fig. 8, leaving on observed area of \( f_{sky} \approx 73\% \). As explained earlier, the key step is the evaluation of LKCs for the masked sphere, which can then be used as input values to predict the LKCs of excursion sets under arbitrary covariance structures. In particular, the input LKCs for the masked sphere have been derived by simulation from a masked single multipole field at \( \ell = 15 \), map; this ensures that the estimation procedure can be implemented with remarkable computational efficiency. The resulting values are then inserted to obtain the analytic predictions at any frequency or multipole.

In Figs. 9 and 10 we compare the masked Gaussian field analytical result with the corresponding simulations in multipole and needlet space, respectively. Of course, here as for the other cases the most relevant results in practice are those for needlets, because single multipoles cannot be extracted from masked data; nevertheless, it is reassuring that the fit works in both circumstances. Moreover, the analysis of multipole components can be exploited to verify the statistical properties of full-sky maps, as those obtained for instance by means of inpainting techniques. These issues are left as topics for further research.

VI. SUMMARY AND CONCLUSION

In this paper, we illustrated a number of applications for cosmological data analysis of the GKF (see [19–23]). The GKF allows us to evaluate exact expected values for Lipschitz-Killing curvatures (Minkowski functionals) in a number of circumstances of applied interest, covering in particular full-sky experiments (accounting for the geometry of the sphere), nonlinear statistics and masked data.

We used the GKF on random fields derived by harmonic and needlet transforms, allowing for the further advantage of better control of cosmic variance effects and localization. In particular we provided the analytic expressions for the Minkowski functionals for needlets and single multipole fields, covering Gaussian and non-Gaussian circumstances, with and without masks. All the results reported are validated by an extensive Monte Carlo study, which demonstrates an extremely good agreement between predictions and simulations.

Many issues in this paper are left open for future research. In particular, while the results we presented provide a rather complete characterization of expected values under a variety of different circumstances, an equally rigorous analysis of error bars is still lacking, even in the mathematical literature (see [44] for some very recent preliminary results). Likewise, we remark that we analyzed here statistics resulting from nonlinear transforms of Gaussian fields, as those arising by tests on power asymmetries and directional variations of the bispectrum in CMB data analysis; other forms of non-Gaussianities are currently beyond the scope of the GKF. We also stress that applications of GKF to settings other than CMB are possible; in particular, it is certainly of interest to extend the techniques discussed here to three-dimensional data sets emerging from large scale structure surveys or to spin random fields from polarization or weak gravitational lensing experiments [45]. Research in this area is currently ongoing and will be reported in future works.

APPENDIX MATHEMATICAL APPENDIX

On a general, high-dimensional manifold, the LKCs for the region \( A \) are defined as the coefficients of a Taylor expansion of a \textit{tube} of radius \( r \) around \( A \). Formally, a tube is simply the set \( A \) plus a halo, i.e.

\[
\text{Tube}(A, r) = \{ x : d(x, A) \leq r \}.
\] (A1)

Assuming that \( A \) had dimension \( \dim(A) = n \), the LKCs are implicitly defined by the formula

\[
\text{Vol}[\text{Tube}(A, r)] = \sum_{k=0}^{n} \mathcal{L}_{n-k}(A) \omega_{k} r^{k}.
\] (A2)

For instance, let \( A \) be the unit square on the plane; by elementary geometry, the volume of the Tube is then given by

\[
\mathcal{L}_{2}(A) + 2 \mathcal{L}_{1}(A) r + \mathcal{L}_{0}(A) \pi r^{2} = 1 + 2 \cdot 2 \cdot r + \pi r^{2},
\] (A3)

whence it is seen that in the two-dimensional case the LKCs correspond to the Euler-Poincaré characteristic, half the boundary length and area, respectively; the general relationship with standard Minkowski functionals is given by

\[
\mathcal{L}_{j}(A) = \frac{1}{(N-j)! \omega_{N-j}} \mathcal{M}_{N-j}(A)
\] (A4)

where here \( N = \dim(A) \). All these definitions extend to arbitrary manifolds and dimensions, and make it possible to express the GKF in much greater generality. Similarly, one can introduce the \textit{Gaussian Minkowski functionals} \( \mathcal{M}^{G}_{k}(U) \) as the Taylor coefficients in the expansion of the Tube probabilities, e.g.
The left-hand side simply represents the probability that a zero-mean standard Gaussian variable belongs to Tube($U$, $r$); for instance, for $U = [u, \infty)$ it can be checked that the Gaussian Minkowski functionals yield the $k$-order derivatives of Gaussian densities that we recalled above. More general forms of $U$ are necessary, however, when one considers non-Gaussian processes, as we shall do below.

We shall now discuss the GKF for the case of nonlinear transforms of Gaussian and isotropic random fields; i.e., we shall consider fields of the form

$$y(x) = g(T(x)).$$

where $T(x)$ is zero mean, unit variance, Gaussian and isotropic, and the function $g(\cdot)$ is such that also $y(\cdot)$ has finite variance; for our purposes, the examples we shall consider are simply quadratic and cubic polynomials, i.e. $g(T) = T^2$ and $g(T) = T^3$. Under these circumstances, the GKF takes the form

$$\lambda^{(i)} \mathbb{L}(\Lambda_u(\beta(x), M)) = \sum_{k=0}^{\dim(M)-i} \lambda^{(i+k)/2} \mathbb{L}_{i+k}(M) \mathcal{M}_k([u, \infty));$$

(A7)

the expression obviously becomes identical to (15), in the Gaussian case $g(T(x)) = T(x)$. For more general transforms, the role of the Gaussian Minkowski functionals becomes crucial: these are rather simple to evaluate for quadratic and cubic cases, as we shall show below.

A. The quadratic case

Here we are interested in the analysis of quadratic functionals such as

$$g(\beta(x)) = \frac{\beta^2(x)}{\|\beta(x)\|^2}.$$  

(A8)

By the general GKF and simple computations we have

$$\mathbb{L}_0(\Lambda_u(\beta(x)), S^2) = \sum_{k=0}^2 (2\pi)^{-k/2} \lambda_j^{(k/2)} \mathcal{L}_k(S^2) \mathcal{M}_k([-\infty, \cdots, -\sqrt{u}) \cup (\sqrt{u}, \infty))$$

$$= \sum_{k=0}^2 (2\pi)^{-k/2} \lambda_j^{(k/2)} \mathcal{L}_k(S^2) 2 \mathcal{M}_k(\sqrt{u}, \infty))$$

$$= 2 \cdot 2 \cdot (1 - \Phi(\sqrt{u})) + \frac{1}{2\pi} \mathbb{L}_2(\beta(x)) \frac{e^{-u/2}}{\sqrt{2\pi}} 2 \sqrt{u}$$

(A9)

$$= 2 \cdot 2 \cdot (1 - \Phi(\sqrt{u})) + \frac{1}{2\pi} \sum_{c} b^2(\frac{\epsilon}{\sqrt{C}}) e^{-\frac{(\epsilon + 1)^2}{4\pi}} L_2(S^2) \frac{e^{-u/2}}{\sqrt{2\pi}} 2 \sqrt{u}.$$  

(A10)

Also

$$\lambda_j^{(1/2)} \mathbb{L}_1(\Lambda_u(\beta(x)), S^2) = \sum_{k=0}^1 (2\pi)^{-k/2} \left[ \begin{array}{c} k + 1 \\ k \end{array} \right] \lambda_j^{(k+1)/2} \mathcal{L}_{k+1}(S^2) \mathcal{M}_k([u, \infty))$$

$$= \lambda_j^{(1/2)} \mathbb{L}_1(S^2) \mathcal{M}_0([-\infty, \cdots, -\sqrt{u}) \cup (\sqrt{u}, \infty))$$

$$+ (2\pi)^{-1/2} \frac{\pi}{2} \lambda_j^{(1/2)} \mathbb{L}_2(S^2) \mathcal{M}_1([-\infty, \cdots, -\sqrt{u}) \cup (\sqrt{u}, \infty))$$

$$= (2\pi)^{-1/2} \frac{\pi}{2} \left[ 4\pi \sum_{c} b^2(\frac{\epsilon}{\sqrt{C}}) e^{-\frac{(\epsilon + 1)^2}{4\pi}} C_{C_{\epsilon}} e^{-\frac{(\epsilon + 1)^2}{4\pi}} \right] e^{-u/2} \sqrt{2\pi}$$

$$= 2\pi \left( \sum_{c} b^2(\frac{\epsilon}{\sqrt{C}}) e^{-\frac{(\epsilon + 1)^2}{4\pi}} C_{C_{\epsilon}} e^{-\frac{(\epsilon + 1)^2}{4\pi}} \right) e^{-u/2},$$

where $C_{\epsilon}$ and $C_{\epsilon}$ are such that also $y(\cdot)$ has finite variance; for our purposes, the examples we shall consider are simply quadratic and cubic polynomials, i.e. $g(T) = T^2$ and $g(T) = T^3$. Under these circumstances, the GKF takes the form

$$\lambda^{(i)} \mathbb{L}(\Lambda_u(\beta(x), M)) = \sum_{k=0}^{\dim(M)-i} \lambda^{(i+k)/2} \mathbb{L}_{i+k}(M) \mathcal{M}_k([u, \infty));$$

(A7)
Finally

\[ \mathbb{E}L_1(A_u(g(\beta_j(x)), S^2)) = 2\pi \left\{ \sum_{\ell} b^2(\ell B^2/4\pi \cdot C_\ell \ell^{(\ell+1)}/2) \right\} e^{-u/2} \]  \hspace{1cm} (A11)

entailing a length of the boundary of excursion sets given by

\[ 2\pi \left\{ \sum_{\ell} b^2(\ell B^2/4\pi \cdot C_\ell \ell^{(\ell+1)}/2) \right\} e^{-u/2}. \]  \hspace{1cm} (A12)

Finally

\[ \mathbb{E}L_0(A_u(\beta_j^3(x)); S^2)) = \sum_{k=0}^2 (2\pi)^{-k/2} L_k(S^2) \mathcal{M}_k((\sqrt{u}, \infty)) = 2(1 - \Phi(\sqrt{u})) + 2 \left\{ \sum_{\ell} b^2(\ell B^2/4\pi \cdot C_\ell \ell^{(\ell+1)}/2) \right\} e^{-(\sqrt{u})^2}/2 \sqrt{2\pi} \sqrt{u}, \]

and likewise

\[ \mathbb{E}L_1(A_u(\beta_j^3(x)); S^2)) = 2\pi \left\{ \sum_{\ell} b^2(\ell B^2/4\pi \cdot C_\ell \ell^{(\ell+1)}/2) \right\} e^{-(\sqrt{u})^2}/2. \]  \hspace{1cm} (A13)

Finally

\[ \mathbb{E}L_2(A_u(\beta_j^3(x)); S^2)) = 4\pi (1 - \Phi(\sqrt{u})). \]  \hspace{1cm} (A15)
